During the period 1952-1968 a total of 462 patients with tumours of the parotid gland were subjected to operation in the Department of Otolaryngology Rikshospitalet, Oslo. In three cases, histological examination revealed lipomatosis of the parotid gland associated with local subcutaneously increased fat deposits.

Case 1 A girl aged 17 years of healthy family was admitted to the department on Nov. 16 1967 for treatment of tumour of the right parotid gland. There were no remarks on prepubertal birth or neonatal period. She had been in good health with normal growth and development. In November 1966 the parents discovered swelling in front of the right ear. An older sister suffered from epidemic parotitis at that time, and so the swelling was considered to be of infectious origin. As the swelling did not disappear but contrarily slowly increased in size, the patient was referred to our department.

Physical examination showed a firm, non-tender smooth tumour apparently spreading the skin and the glandular tissue extending from the right mandibular angle to the zygomatic arch. The parotid duct and the secretion seemed unaffected. No parathyroid gland involvement and no lesion of facial nerve were seen. The results of routine laboratory studies, including blood-cell counts and paper electrophoresis of serum proteins were normal. Sialographically the tumour was seen to be closely connected laterally with the parotid gland.

After observation for 3 months in our out-patient clinic, the tumour appeared to increase in size with distinct infiltration of the skin. Subtotal parotidectomy and extirpation of the tumour were performed. The operation revealed a yellowish firm tissue forming tumour-like mass with infiltration into the parotid gland and the overlying fatty tissue.

Histological examination showed lobular glandular architecture with islands of acinar cells surrounded by numerous large fat cells. The ductal system seemed normal, perhaps with some proliferation of small ducts. Angioma-like proliferation was not seen (Fig. 1).

Case 2 A woman, aged 43 married, four children, several abortions, operatively sterilized, of healthy ancestry.

The patient was admitted to the department on June 14 1968, for surgical treatment of tumour in the right parotid gland, apically developed.

Clinical examination showed a 3 x 4 cm, non-tender firm, movable tumour relatively well demarcated, in the right parotid area. The parotid duct and the secretion seemed normal. There was no parathyroid growth, no involvement of the facial nerve.

The results of routine laboratory studies were normal. Sialography confirmed the diagnosis of tumour laterally in the parotid gland.

Operation disclosed fairly well circumscribed, partially encapsulated yellowish tumour of firm consistency. Histological examination revealed lipomatosis of the parotid tissue. Acinar cells formed small strands and islands between large fat cells, which appeared to have replaced most of the normal acinar cells. The ductal system seemed largely normal, perhaps with some proliferation of smaller ducts. Angioma-like proliferation was not seen (Fig. 2).

Case 3 A married woman, aged 36, one child, was admitted for operative treatment of repeated recur-

rence of a tumour of the right parotid gland on Oct 15 1967

The first appearance of the tumour was recorded in 1953. A non-tender firm, ill-defined tumour had developed within a few weeks in front of the right ear. The tumour was removed in the autumn of 1953. Histological diagnosis was lipoma. The tumour recurred and re-operations were performed in 1957, 1958 and 1965.

On admission in 1967 clinical examination showed a diffuse swelling of the right cheek involving the parotid gland. The consistency of the infiltrate was partially firm, partially soft, with nodular and flat non-tender areas. Secretion from the parotid duct could not be provoked. There were no parapharyngeal growth and no marked functional facial-nerve disorders.

The result of routine laboratory studies were normal. Extirpation of tumour and parotidectomy were performed. Histological examination showed atrophic

glandular tissue with chronic inflammation, pronounced proliferation of small ducts and only a few pyknotic acinar cells. The main architecture of the lobular structure was preserved, with septa of dense fibrous connective tissue surrounding masses of large fat cells, ductules and inflammatory cells. No atypical cells were seen.

Histochemical analysis of the tissue mainly showed triglycerides.

Lately a sixth recurrence with the same tumour like development has appeared.

DISCUSSION

In these three patients, a local lipomatosis of the right parotid gland was found without relation to general adiposity. Histologically it appeared to be a degenerative process in the glandular secretory epithelium with fatty transformation. This view is supported by the findings of accumulations of fat in individual acinar cells (Fig. 4).

In the periglandular tissue we found an increased number of large fat cells. The aetiology of the disease is obscure. Rauch (1959) gave a detailed description of sialoses, defining them as metabolic disorders related to allergic, hormonal, neurovegetative disturbances and nutritional deficiency. A hormonal background is mentioned by several authors (Kopp, 1953; Hall, 1959). The progress in the field of lipogenic research documenting a high potential activity of lipoid tissue might explain a rapid

Fig. 3. Lipomatosis of the parotid gland. Lobular architecture. Centrally ductal proliferation, single pyknotic acinar cells surrounded by several inflammatory cells and numerous fat cells (Case 3).

transformation of the parotid gland. Empirically we know that the physiological involution of the parotid gland takes place through a lipomatous degeneration. In the other salivary glands, this process is brought about by fibrosis.

The surgical treatment of lipomatosis in our patients did not arrest the disease. In comparison, it may be mentioned that in cases of clear-cut lipomata, no recurrence was seen.

Reports on lipomatosis of the parotid gland are few and our knowledge of this disease is

limited. We believe that further studies of the problem by histochemical and biochemical methods may throw light on the problems involved.

CYLINDROMA OF SALIVARY GLANDS

A REPORT OF 80 CASES

P Berdal A de Besche and E Myllus

From the Department of Otolaryngology Rikshospitalet Oslo and the Department of Pathology Sentralkrkehuset Trondheim Norway

Eighty cases of cylindroma (adenoid cystic carcinoma) from the Department of Otolaryngology Rikshospitalet Oslo are reviewed. Clinical and histological characteristics are discussed. Special attention is drawn to a tendency to involvement of nerves.

Cylindroma (Billroth 1859) synonym adenoid cystic carcinoma (Ewing, 1928) is a malignant epithelial tumour which develops in large and small salivary glands. In Norway cylindroma is notified to the Register of Cancer and constitutes about 1.15 per thousand of all malignant tumours (within the 10-year period from 1956 to 1965 115 cases of cylindroma. Total number of new cases of cancer all types, about 100 000).

To illustrate some of the clinical features of cylindroma 80 cases from the Department of Otolaryngology Rikshospitalet Oslo are briefly mentioned below. The patients were seen during the years 1952-68.

Most patients were between 40 and 50 years of age when the first symptom of disease was observed. No sex-difference.

The duration of disease is shown in Fig. 1. It shows the intervals between the onset of symptoms until the diagnosis was made, and how long the patients have been living with the disease after the diagnosis was made and therapy started. Thirty three patients died of cylindroma. Three patients died of cerebral haemorrhage. Twenty-two are alive and without signs of recurrence after more than 5 years. Twenty two patients are alive and fairly well with recurrence and/or metastases.

Among many distinctive features of cylindroma we particularly want to point at a marked tendency of the tumour to perineural and intraneural growth (Fig. 2) and to clinical symptoms from sensory and motor nerves.

Before the diagnosis was established several of our patients had been treated for many years for pain in the trigeminal area. In some of the cases the pain was very severe and could not be relieved by analgesics. That the diagnosis was made relatively late in these cases may be ascribed partly to a macroscopically minimal neoplastic infiltration and partly to inadequate knowledge of this type of tumour. Paresis of the facial nerve and hypoglossal nerve has also been present in cylindroma patients for a long time before the diagnosis was made.

It appears that the cylindroma also has a tendency to perivascular and intravascular growth (Fig. 3). However the perivascular growth is not seen so frequently or is not so marked as in the perineural area. The peri-

D Date of Diagnosis M Metastases

Fig 1 Duration of disease

vascular infiltration may be responsible for the development of ectatic vessels which can often be seen in the skin and mucous membrane covering the tumour

Intravascular growth of the tumour at an early stage probably explains why haematogenous metastases appear more frequently and

also earlier than lymphatic metastases and may occur many years after the extirpation of the primary tumour

Histologically it is noticed that only minimal infiltration by lymphocytes and macrophages occurs. Usually there are neither necrosis nor bleeding in the tissue of the tumour. These

Fig. 2. Perineural growth of cylindroma

Fig. 3. Perivascular growth of cylindroma.

features may to some extent, explain why cylindromata rarely ulcerate in spite of infiltration of the mucous membrane or skin.

In the treatment it may be necessary in the individual patient in the long run to apply both surgery and radiological and chemotherapeutic methods.

Extirpation of the tumour will, in most cases, be the principal treatment, aiming at radical removal. In spite of surgical removal which may appear to be radical a new tumour is often seen close to or far from the original site due to the tendency of the tumour to infiltrate long nerves and blood vessels. Electrocoagulation of the tumour may be appropriate in the trachea and bronchi.

Concerning radiological treatment, it has been emphasized by many authors that the cylindroma is radioresistant. In our opinion this view is too categorical. Some years ago we were of the same opinion. Later we have, in many

cases, seen a temporary good effect of X-ray treatment. From a radiotherapeutic point of view a cylindroma may be looked upon as radiosensitive, but not radiocurable. Lack of radiocurability may to some extent be connected with its peculiar way of growth along nerves and vessels, resulting in infiltration far away from the primary tumour. Thus, it may happen that the irradiation fields do not cover the entire tumour area.

Chemotherapy has been tried in a few cases. In two cases, Vinblastin (Velbe, Lilly) probably retarded the growth of the tumour as judged from the growth or pulmonary metastases. Methyldrazin (Natulan, Roche) seems to have a more pronounced cytostatic effect than Velbe.

Corticosteroids seem to exert a favourable influence both on the growth of tumour and the general condition of the patient. We have used steroids in advanced cases only.

The prognosis is not very good. Many patients died of their cylindroma, but we have also seen 22 cases which appear to be cured with no recurrence after 5 years or more. Of these, six have been free from recurrences for periods from 10 to 17 years. In predicting the prognosis, it should be borne in mind that the general state of health and the capacity for work may be only slightly affected for a long time, often for several years, even in patients with multiple and major pulmonary metastases. We do not know of any other malignant epithelial tumour than cylindroma, with which the patient can survive with his disease for a long time and to enjoy subjective well-being.

DISCUSSION

C. M. Eserich: The term adenoid cystic carcinoma is nowadays much more used for this type of tumour because cylindroma is a diffuse conception, indicating several independent types of tumour with cylindromatous structures, but even adenoid cystic carcinoma is to some degree a misleading description, as cystic structures are not typical in this type of tumour as in papillary cystadenolymphoma and muco-epidermoid carcinoma.

A series of about 1700 parotid tumours (300 malignant) treated at Karolinska Sjukhuset confirms that adenoid cystic carcinoma has a special tendency to neural invasion. Thus, perineural and intraneural growth of the tumour caus-

Table 1 Spontaneous paralysis of the facial nerve by different types of parotid tumour (1678 cases)

Solid poorly differentiated carcinoma	24

ing spontaneous paralysis of the facial nerve occurred in 29 % of the cases with adenoid cystic carcinoma. A comparison with other types of parotid tumours appears from the table.

Spontaneous paralysis of the facial nerve proved to imply a hopeless prognosis, as all these patients died in tumour disease: all of them within 8 years of the onset of the paralysis. Adenoid cystic carcinoma is characterized by a prolonged clinical course, often with late appearance of recurrences and metastatic spread. The long-term prognosis is grave and an analysis of more than 2500 salivary gland tumours has shown that a much longer follow-up than 5 years is necessary to disclose the definite prognosis in adenoid cystic carcinoma. We have found, however, that there is a difference between adenoid cystic carcinomata, which are dominated by a cribriform component (low-grade malignant) and those which are dominated by a solid component (high-grade malignant). In rapidly growing tumours, such as solid adenoid cystic carcinoma, epidermoid carcinoma and undifferentiated carcinoma, the poor prognosis is already evident from a 5-year follow-up. A much longer follow-up is, on the other hand, necessary to disclose the definite prognosis in more slow-growing tumours, such as adenoid cystic carcinoma dominated by the cribriform component.

INCIDENCE AND PROGNOSIS OF SALIVARY-GLAND TUMOURS AT DIFFERENT SITES

A STUDY OF PAROTID SUBMANDIBULAR AND PALATAL TUMOURS IN 2632 PATIENTS

C. M. Eneroth

*From the Department of Otolaryngology and the Institute of Tumour Pathology
Karolinska Hospital Stockholm Sweden*

In a histological re-examination and re-classification of 2632 palpable lesions of the parotid submandibular and palate regions, 2311 exhibited the structures characteristic of true salivary-gland tumours. Tumours originating in the various major and minor salivary glands have essentially similar histological features. The relative incidence of the different types of true salivary gland tumours and their prognosis have been shown to vary with their location. One out of six salivary gland tumours in the parotid gland, one of three in the submandibular gland and almost half of the tumours in the palate proved to be malignant. A long-term clinical follow-up study revealed a difference in prognosis for a given type of malignant salivary gland tumour at various sites. The prognosis seems best when the primary tumour is located in the palate less favourable when it is in the parotid gland, and least favourable in the submandibular gland.

Tumours originating in the various major and minor salivary glands have essentially similar histological features. The purpose of this study is to determine whether the incidence of the various types of tumour and their prognosis vary with the location.

The three most common sites of involvement for salivary gland tumours are the parotid and submandibular glands and minor salivary glands of the palate. About 95 % of all salivary gland tumours are considered to be located at these sites, whereas the remaining 5 % are found in other minor salivary glands than those of the palate and in the major sublingual glands (Seifert, 1966). Although there is an extensive literature on these tumours, no large operative series treated in the same clinic has been described, especially as regards the submandibular and minor salivary-gland tumours. This is largely due to the fact that these

tumours are relatively uncommon. As a consequence, it is very difficult to compare the incidence of various types of tumour and their prognosis in different locations.

To carry out a comparative study of this kind one must have not only data concerning a large number of operated tumours in various locations, but also a meticulous long term clinical follow up study. In order to compare the histological and clinical features and the prognosis of salivary-gland tumours in various locations in as many cases as possible a study of tumours was made in the three locations where most salivary-gland tumours occur, i.e. in the parotid and the submandibular gland and the palate region.

MATERIAL

The study is based on a histological and clinical survey of parotid, submandibular and palate tumours in 2632 patients treated in the Department of Otolaryngology and Radiumhemmet, Karolinska Sjukhuset, during the period 1909-1965 (only a few cases in the series were treated before 1925).

A histological reclassification of all tumours was made as well as a complete long-term clinical follow up study starting with the first histological verification of the tumour. A rough estimate of the prognosis is obtained by the incidence of metastases and by calculation of the determinate survival rate (D. S. R.) during a follow-up period of 5-40 years. D. S. R. in

Table 1 *Reclassified tumours of the parotid gland the submandibular gland and the palate region (2632 patients). Distribution of salivary gland tumours in these locations.*

Location	Total No. of tumours	Salivary-gland tumours	
		No.	%

Submandibular gland	187	161	86
Palate	378	167	44
Total	2632	2311	

plies that the survival rate is based on determinate groups, which do not include patients lost to follow-up or those dying without signs of tumour disease. Since no patient in the follow-up series was lost, the D. S. R. is thus based on mortality in the tumour disease.

RESULTS

In each of the three locations examined, a palpable lesion consists in varying degrees of a true salivary-gland tumour. Table 1 shows that a "tumour" of the parotid and submandibular glands generally is a true salivary-gland tumour—in the parotid almost always (96 %) and in the submandibular in five cases out of six. In the palate, however not even half of all tumours are true salivary-gland tumours.

The difference in incidence between the palate and the major salivary glands (parotid and submandibular) can to some extent be explained on histogenetical grounds. A very large proportion of "tumours" in the palate thus originate from the squamous epithelium of the mucous membrane (142 tumours). In the major salivary glands, however there are also tumours that do not arise in the actual salivary-gland parenchyma. These include mesenchymal tumours and so-called pseudotumours, i.e. localized swellings of varying origin, such as inflammation, hyperplasia and cyst formation.

As regards the distribution of true salivary gland tumours in various locations, the incidence is strikingly high in the parotid as compared with the other locations. The fact that a salivary-gland tumour is 12 times as frequent in the parotid as in the submandibular gland is difficult to explain histogenetically. The difference cannot be based on size alone because the two parotids weigh 40–60 g, while the two submandibular glands weigh 20–30 g (Scifert, 1966). According to Durrani (1964) this large difference between the incidence in the two glands suggests that there must be some factors at work that make the parotid more susceptible to tumours than the submandibular gland.

The distribution of various types of true salivary-gland tumours in various locations is shown in Table 2. It will be seen that true salivary-gland tumours include a large number of types. There is, however a striking predominance of a single type of tumour—namely pleomorphic adenoma (previously termed benign mixed tumour) four out of five salivary gland tumours of the parotid gland and more than half of tumours of the submandibular gland and the palate thus fall under the heading of pleomorphic adenoma.

As regards malignant tumours of the salivary glands, there is a remarkable difference in the incidence of adenoid cystic carcinoma in the various locations. 2 % 16 % 22 %

Why is the relative incidence of this type of tumour eight times higher in the submandibular gland than in the parotid gland? Can there be a histogenetical explanation? In the palate, two types of tumour strongly predominate—muco-epidermoid and adenoid cystic carcinoma. In the submandibular and, particularly in the parotid gland the malignant salivary-gland tumours are more evenly distributed among the different types.

Differences in histology may provide an explanation of differences in incidence between various types of tumour in various locations. This is easy to understand when a comparison is made between major and minor salivary

Table 2 *Reclassified salivary gland tumours of the parotid gland the submandibular gland and the palate (2311 patients) Distribution of different types in these locations*

Type of tumour	Parotid gland	Submandibular gland	Palate

Total	1983	161	167

glands. A comparison between the parotid and the submandibular glands, however reveals differences not only in the acini—the parotid gland being composed entirely of serous cells, whereas the submandibular gland contains mucous cells as well as serous cells, but also a histological difference in the duct system (Rother 1963).

If the various types of true salivary-gland tumours are divided into a benign and a malignant group, it appears from Table 3 that the incidence of malignancy is lowest in the

parotid gland and highest in the palate. Thus, about one out of six tumours in the parotid gland, one of three in the submandibular gland and almost half of the tumours in the palate are malignant. It is noteworthy that the relative incidence of malignant tumours of the salivary glands is twice as high in the submandibular as in the parotid gland.

Departing for a moment from true salivary gland tumours, I should here like to consider the incidence of malignancy of all tumours in the three locations, thus including not only tumours of the salivary-gland type but also "pseudotumours" and tumours that do not arise in the actual salivary gland parenchyma. It must be of interest from the clinical viewpoint to determine how great the risk is that a tumour occurring in the parotid, submandibular or palatal region will be malignant. Table 4 shows that about one out of six tumours in the parotid gland, one of three in the submandibular gland and more than half of all tumours in the palate are malignant. The incidence of malignancy in the total tumour and the true salivary gland tumour material, respectively is in good agreement as regards parotid and submandibular tumours (cf Tables 3 and 4). In the palate, on the other hand

Table 3 *Reclassified salivary gland tumours of the parotid gland the submandibular gland and the palate region (2311 patients) Distribution of malignant salivary gland tumours in these locations*

Submandibular gland	187	62	33
Palate	378	217	57
Total	2632	638	

the risk of malignancy is greater in cases of palpable lesion than when a true salivary-gland tumour is present. To some extent this is due naturally to the large number of squamous-cell carcinomata in the palate (122 cases).

It is not known whether and to what extent the prognosis varies when the same type of malignant tumour occurs in different locations. Prognoses for various kinds of malignant tumours in various locations have been determined by a study of the incidence of metastases and the determinate survival rate (D.S.R.) over a long follow-up period.

In spite of the fact that the present series is larger than any previously reported, most of the groups of salivary-gland tumours located in the submandibular gland and the palatal region are too small to be discussed in this connection. No conclusions on the prognosis

have been drawn when the tumour groups consisted of fewer than 10 cases.

The incidence of metastases of different types of tumours in different locations is shown in Table 5

X indicates those groups which are considered too small to merit discussion. Only one type of tumour i.e., adenoid cystic carcinoma occurs in sufficient numbers in all three locations to justify conclusions based on a comparison. The incidence of metastases is considerably higher when the primary tumour is located in the submandibular gland than in the parotid gland or the palate. Thus, adenoid cystic carcinoma metastasizes more than twice as often when located in the submandibular gland as in the palate.

It is apparent that an increased incidence of metastases is associated with a poorer prognosis. This is shown in Fig. 1 which gives the determinate survival rate (D.S.R.) for adenoid cystic carcinoma in various locations. When the primary tumour is located in the palate, the prognosis is best. When it is located in the parotid gland, the prognosis becomes worse, and in the submandibular gland worst. In other words, the prognosis is aggravated in parallel with an increased incidence of metastases (Table 5).

The incidence of metastases and consequently the prognosis of a given type of tumour are influenced by various factors, such as the drainage of lymph from the primary tumour lo-

Table 5 *Malignant salivary-gland tumours of the parotid gland the submandibular gland and the palate: Incidence of metastases during the follow-up period (X replaces figures too small to be discussed in this connection)*

Fig. 2. Relation between duration of observation and determinate survival rate of solid undifferentiated carcinoma of the parotid and submandibular gland.

cation and the pre-operative duration of symptoms. The longer the interval between the onset of symptoms and the treatment of the malignant tumour the greater the risk of metastases and as a consequence the worse the prognosis. The correspondence between the pre-operative duration of the tumour increased incidence of metastases and worsening of the prognosis is clearly evident from the study of cases of adenoid cystic carcinoma in various locations, in which the pre-operative duration of symptoms averaged 1.9 years in the palate, 3.7 years in the parotid and 5.6 years in the submandibular gland.

That the prognosis is worse when a given type of tumour is located in the submandibular rather than in the parotid gland is clear from Fig. 2, which shows the D.S.R. for solid undifferentiated carcinoma after 5, 10, 15 and 20 years in these locations.

The results of the long-term clinical follow up study suggest that the prognosis for a given type of malignant tumour varies according to its location. Moreover the prognosis seems most favourable when the primary tumour is in the palate, less favourable when it is in the parotid gland and least favourable in the submandibular gland.

TUMOURS OF THE PALATE

L. Hjertman and C. M. Eneroth

*From the Department of Otolaryngology and the Institute of Tumour Pathology
Karolinska Hospital, Stockholm, Sweden*

A histological reclassification of 383 tumours of the palate showed that salivary-gland tumours and epidermoid carcinoma constituted the two largest groups, with 170 and 123 cases, respectively. Of the total number 219 cases were malignant, which means that the risk of palatal tumour being malignant is 57 %. A long-term clinical follow-up study disclosed much better prognosis for the malignant salivary gland tumours than for the epidermoid carcinoma. In the latter group of tumours, the incidence of ulceration was much higher. The presence of ulceration in tumour of the palate may therefore be considered to indicate an unfavourable prognosis. Salivary-gland tumours were more commonly found in the hard palate, and epidermoid carcinoma in the soft palate.

In the palate, a wide variety of tumours may develop, originating in the epithelium, the connective tissue and the minor salivary glands. Most studies of salivary-gland tumours are concerned with tumours in the major salivary glands, while those dealing with tumours in the minor salivary glands are relatively few. This situation is hardly surprising, since only about 10 % of the relatively rare salivary gland tumours are considered to originate in the minor salivary glands (Selfert, 1966). It is, therefore, difficult to collect any considerable quantity of these tumours. More than half of the intra-oral salivary-gland tumours appear in the palate (Lucas, 1964), which means that the palate is the most common location for these tumours. We have accordingly chosen the palatal tumours as the subject for a histological and clinical study. For the clinical evaluation a long-term follow-up study is of great value, particularly as only a few similar examinations

covering a large number of palatal tumours have been reported.

MATERIAL

The present study is based on a analysis of all histologically verified tumours of the palate in 383 patients, registered at Radiumhemmet during the period 1919-1966. A histological re-examination was made of all the tumours, which were then reclassified according to a more differentiated nomenclature (Foots & Frazell, 1954; Eneroth, 1964). With a few exceptions, all the patients were re-examined regularly and it was therefore possible to carry out a histological and clinical correlation study. The prognosis was established by studying the determinate survival rate, which is based on determinate groups. The determinate groups do not include patients lost to follow-up and those dying of intercurrent disease.

RESULTS

In the histological reclassification, the 383 palatal tumours were distributed according to the various types shown in Table 1. Salivary-gland tumours occurred in 170 cases, i.e. 44 % of the total number of palatal tumours. They were benign in 95 and malignant in 75 cases. Squamous-cell tumours occurred in 143 cases. The 20 benign tumours in this group were all papillomata, while the 123 malignant were all epidermoid carcinoma. Thirty-three tumours

were mesenchymal 20 being benign and 13 malignant. The series included eight cases of malignant melanoma, a type of tumour which very rarely occurs in the oral cavity. According to the Swedish Cancer Register there were only four diagnosed cases of malignant melanoma in the oral cavity during the 5 year period 1958-1962. All the tumours in the present study were clinically considered to be neoplasms prior to the histological examination. However 29 cases turned out to be due to a non-neoplastic disease, i.e. a localized mass of varying nature for example, hyperplasia or granuloma.

The distribution according to the type of sa-

livary gland tumour is shown in Table 2. All of the 95 benign salivary gland tumours were pleomorphic adenomata and they constituted 56 % of the total number of salivary-gland tumours. In a strikingly large proportion of the pleomorphic adenomata, the structure was to uniformly epithelial that the tumours could be classified as monomorphic adenomata. Malignant salivary-gland tumours occurred in 75 cases, and the two preponderant types of tumour were muco-epidermoid carcinoma and adenoid cystic carcinoma, with 27 and 37 cases, respectively. Together these two types accounted for 85 % of all the malignant salivary gland tumours of the palate. The other malignant tumours of the salivary glands, acinic cell carcinoma, mucus-producing adenopapillary carcinoma, solid undifferentiated carcinoma and carcinoma in pleomorphic adenoma constituted altogether only 11 cases.

Table 3 shows the distribution of the mesenchymal tumours. Of the 20 benign tumours, 14 were polypoid fibroma or angiofibroma, and of the 13 malignant seven were malignant lymphoma. Other types of mesenchymal tumours occurred only in isolated cases.

The incidence of malignant tumours of the palate varies considerably in different series. Thus, according to Dahlin (1968) it was 34 % and according to Boyle & Cole (1968) 75 %. In the present study there was a 57 % risk

Table 4 Follow-up study of malignant salivary gland tumours and epidermoid carcinomata of the palate

Observation period (years)	Determinate survival rate, %	
	Malignant salivary-gland tumour	Epidermoid carcinoma
5	77	41
10	61	30
15	53	22
20	50	13

that a tumour of the palate was malignant. The two principal groups of malignant tumours are the malignant salivary-gland tumours and the epidermoid carcinomata, which together make up 90 % of all malignant tumours of the palate. These two groups reveal a definite difference in prognosis, as shown in Table 4. As regards the malignant salivary-gland tumours the determinate survival rate drops from 77 % in the 5-year group to 50 % in the 20-year group. The corresponding figures for epidermoid carcinomata are 41 % and 13 % respectively. The prognosis is thus poorer for epidermoid carcinomata.

Is there any clinical evidence of malignancy when a neoplastic change is found in the palate? A pigmented, easily bleeding, ulcerated tumour of the palate should give a strong suspicion of a highly malignant tumour. In all

eight cases of malignant melanoma in the present study the tumour had these characteristics, and all these patients died of the tumour disease within 5 years.

Table 5 shows that there is a definite difference in the incidence of ulceration between different groups of malignant tumours of the palate. Ulceration was present in 22 of 75 malignant salivary-gland tumours (29 %) and in 90 of 123 epidermoid carcinomata (73 %). The prognosis in epidermoid carcinoma was considerably worse than in the malignant salivary gland tumours. Ulceration of a tumour of the palate can therefore be considered to indicate an unfavourable prognosis in view of the much higher incidence of ulceration in epidermoid carcinoma than in malignant salivary-gland tumours.

The localization in the palate of the two largest groups of tumours, i.e., the salivary-gland tumours and the epidermoid carcinomata, is shown in Table 6. Of the 170 salivary

Table 5 Frequency of ulceration in malignant salivary-gland tumours and epidermoid carcinomata of the palate

Diagnosis	Total No. of cases	Ulceration No. of cases
Malignant salivary-gland tumour	75	22 (29 %)

Location	Salivary-gland tumour			Epidermoid carcinoma
	Benign No. of cases	Malignant No. of cases	Total No. of cases	No. of cases
Hard palate	60	54	114 (67 %)	48 (39 %)
Soft palate	29	13	44 (26 %)	39 (48 %)
Hard and soft palate	6	6	12	16
Total	95	73	170	123

gland tumours, 114 (67 %) were situated in the hard palate while only 48 (39 %) of the 123 epidermoid carcinomata were found in this region. A difference as regards the localization to the hard or soft palate has accordingly been demonstrated to exist in these two different groups of tumours. The salivary gland tumours were most common in the hard palate while the epidermoid carcinomata were more frequently observed in the soft palate which is in accordance with the observations of Martin (1942).

CYTOLOGICAL DIAGNOSIS OF SALIVARY-GLAND CARCINOMATA FROM ASPIRATION BIOPSY SMEARS

J Zajicek and C.-M. Eneroth

*From the Department of Clinical Cytology the Institute of Tumour Pathology and the
Department of Otorhinolaryngology Karolinska Hospital, Stockholm Sweden*

In 100 consecutive cases of salivary-gland carcinoma in which aspiration biopsy had been performed before operation, the cytological findings were compared with the histological diagnoses. Morphological features are described which should prove useful in the differentiation between various types of salivary-gland carcinoma in smears of aspirate—adenoid cystic, acinic cell, mucous-producing adenopapillary trabecular adenocarcinoma, muco-epidermoid carcinoma and undifferentiated carcinoma.

Malignant epithelial tumours of the salivary glands are commonly classified according to their morphological characteristics in tissue sections as adenocarcinoma of various types, muco-epidermoid carcinoma and undifferentiated carcinoma (Foote & Frazell, 1954; Eneroth, 1964). Studies of the long-term survival rates after treatment for these tumours indicate that the clinical course is dependent on the histological type (Eneroth *et al.*, 1966, 1967; Blanck *et al.* 1967). It may therefore be expected that the treatment of malignant salivary-gland tumours, i.e. the extent of surgery and whether or not pre-operative irradiation is to be given, will increasingly be determined by the type of the neoplasm, which consequently must be known to the clinician.

Aspiration biopsy of salivary-gland tumours with a fine needle (22 gauge) yields material for cytological analysis. Benign neoplasms in these sites, such as oncocytic tumours (papillary cystadenoma lymphomatous and oncocytoma) and mixed tumours can in most cases be recognized from a study of aspiration biopsy smears (Eneroth & Zajicek, 1965, 1966). The present paper is concerned with

the morphology of cells in aspirates from carcinomata of the salivary glands. The cytological slides from 100 such tumours were reviewed. The morphological details which permit identification of the tumours pre-operatively by fine-needle aspiration biopsy are described.

MATERIAL

The 100 tumours were consecutively investigated primary carcinomata of the salivary glands. The diagnosis was histologically established in all cases. The histological types were as follows: adenoid cystic, 31 cases, acinic-cell, 28 mucous-producing adenopapillary 5 trabecular adenocarcinoma, 1 muco-epidermoid carcinoma, 20 and undifferentiated carcinoma, 15 cases (six arising in pleomorphic adenoma).

RESULTS AND CONCLUSIONS

Adenoid cystic carcinoma. The initial cytological reports in the 31 cases of histologically verified adenoid cystic carcinoma are presented in table 1 in which the cases are grouped according to the period during which the aspiration biopsy was performed, viz. 1953-1965 or 1966-1967. Contrary to what might have been expected in adenocarcinomata of "cystic" type, the cytological report stated "cyst" in only one of the 31 cases. "Cystic" is therefore a somewhat misleading description. Abundant neoplastic material was obtained in the other 30 cases. In 14 of them, pleomorphic adenoma (mixed tumour) was reported—13 from 1953-

Table 1 *Initial cytological reports from aspiration biopsy in 31 histologically verified primary adenoid cystic carcinomata*

	1953-1965	1966-1967
Cyst	1	—
Pleomorphic adenoma	13	1
Carcinoma	8	—
Adenoid cystic carcinoma	—	8
Total	22	9

1965 and one in 1966. Carcinoma was cytologically reported in eight cases, all from the first period and the cytological diagnosis was adenoid cystic carcinoma in eight cases, all from 1966-1967.

The cells aspirated from the adenoid cystic carcinomata had round or oval nuclei surrounded by a scarcely detectable rim of cytoplasm (Fig. 1 A). Cell size showed little variation. In addition to tumour cells, cylindrical structures—globules of mucus—were seen in the slides from 18 of the 31 adenoid cystic carcinomata (Fig. 1 A). Such globules were not seen in aspirates from the other salivary-gland tumours, including the pleomorphic adenomata. Their presence may therefore be regarded as indicative of adenoid cystic carcinoma (Eneroth & Zajicek, 1969). This is important when the cytologist is otherwise in doubt as to whether he is dealing with a pleomorphic adenoma (mixed tumour) or a carcinoma. Recognition of malignancy will in such cases be based partly on the cells, but mainly on their mucinous product with its characteristic globules.

The presence of mucus globules suggests that the adenoid cystic carcinoma is of highly differentiated type (Eneroth *et al.* 1967). The predominantly solid, poorly differentiated adenoid cystic carcinomata in this study did not yield such distinct "cystic" (mucoid) aspirate.

In adenoid cystic carcinoma of low differentiation the recognition of malignancy is not difficult, but cytological typing of the tumour

is not always possible. In such cases, the cytologist can only report a carcinoma and the typing must await histological analysis, which may disclose predominantly solid adenoid cystic carcinoma.

Acinic-cell carcinoma. Table 2 shows the initial cytological reports in the 28 cases of acinic-cell carcinoma. Here too, the tumours are grouped according to the time of diagnosis. Benign epithelial tumour usually adenoma, was cytologically reported in 12 cases, 10 of them from the period 1953-1962 and two from 1963-1967. Carcinoma was cytologically suspected in two cases from the first period. Carcinoma without further specification was reported in three cases. Acinic-cell carcinoma was suggested or diagnosed in 11 cases, seven of them from the second period of the study. The review of the slides showed that the smears from acinic-cell carcinomata characteristically contained clusters of cells with central nuclei and abundant foamy cytoplasm. Generally no clear-cut cellular atypia was seen, and the diagnosis was based on the presence of numerous acinic cells in solid plugs with total absence of ductal epithelium (Fig. 1 B).

Other adenocarcinomata. From the five mucus-producing adenopapillary adenocarcinomata and the single trabecular adenocarcinoma, abundant tumour material was obtained. The aspirate consisted partly of plugs of overlapping cells and partly of sheets of cells in more regular arrangement. The individual cells in

1965 and one in 1966. Carcinoma was cytologically reported in eight cases, all from the first period, and the cytological diagnosis was adenoid cystic carcinoma in eight cases, all from 1966-1967.

The cells aspirated from the adenoid cystic carcinomata had round or oval nuclei surrounded by a scarcely detectable rim of cytoplasm (Fig. 1 A). Cell size showed little variation. In addition to tumour cells, cylindrical structures—globules of mucus—were seen in the slides from 18 of the 31 adenoid cystic carcinomata (Fig. 1 A). Such globules were not seen in aspirates from the other salivary gland tumours, including the pleomorphic adenomata. Their presence may therefore be regarded as indicative of adenoid cystic carcinoma (Eneroth & Zajicek 1969). This is important when the cytologist is otherwise in doubt as to whether he is dealing with a pleomorphic adenoma (mixed tumour) or a carcinoma. Recognition of malignancy will in such cases be based partly on the cells, but mainly on their mucinous product with its characteristic globules.

The presence of mucus globules suggests that the adenoid cystic carcinoma is of highly differentiated type (Eneroth *et al.* 1967). The predominantly solid poorly differentiated adenoid cystic carcinomata in this study did not yield such distinct cystic (mucoid) aspirate.

In adenoid cystic carcinoma of low differentiation the recognition of malignancy is not difficult, but cytological typing of the tumour

is not always possible. In such cases, the cytologist can only report a carcinoma and the typing must await histological analysis, which may disclose predominantly solid adenoid cystic carcinoma.

Acinic-cell carcinoma Table 2 shows the initial cytological reports in the 28 cases of acinic-cell carcinoma. Here too, the tumours are grouped according to the time of diagnosis. Benign epithelial tumour—usually adenoma, was cytologically reported in 12 cases, 10 of them from the period 1953-1967 and two from 1963-1967. Carcinoma was cytologically suspected in two cases from the first period. Carcinoma without further specification was reported in three cases. Acinic-cell carcinoma was suggested or diagnosed in 11 cases, seven of them from the second period of the study. The review of the slides showed that the smears from acinic-cell carcinomata characteristically contained clusters of cells with central nuclei and abundant foamy cytoplasm. Generally no clear-cut cellular atypia was seen, and the diagnosis was based on the presence of numerous acinic cells in solid plugs with total absence of ductal epithelium (Fig. 1 B).

Other adenocarcinomata From the five mucus-producing adenopapillary adenocarcinomata and the single trabecular adenocarcinoma, abundant tumour material was obtained. The aspirate consisted partly of plugs of overlapping cells and partly of sheets of cells in more regular arrangement. The individual cells in

May-Grienerwald-Giemsa stain $\times 100$.

the mucus-producing adenocarcinomata exhibited abundant cytoplasm and occasionally contained globules of mucus-like material, which appeared intensively red in MGG-stained smears (Fig. 1 C).

Muco-epidermoid carcinoma. In the muco-epidermoid carcinomata of low malignancy (18 cases) the aspiration biopsy usually yielded cystic fluid containing cell detritus and inflammatory cells, mainly lymphocytes. The carcinoma cells were of monomorphic appearance (Fig. 1 D) and resembled to some extent the oncocytes in papillary cystadenolymphomata. Definitive differentiation towards squamous epithelium was only rarely recognized in the smears. In the muco-epidermoid carcinomata of high malignancy grade (2 cases) by contrast, the cells were markedly polymorphic, and some of them strongly resembled the cells usually aspirated from squamous-cell carcinomata.

One diagnostic difficulty in muco-epidermoid carcinoma of low malignancy is that aspiration not infrequently yields only cystic fluid (in seven of our 18 cases). A cytological report of acellular fluid thus does not preclude tumour. However when the fluid has been removed by aspiration, the clinical observations can be re-assessed. If the swelling disappears and other palpatory findings return to normal, the patient may as a rule, be freed from follow-up. But if any suspicion of a lesion remains, the aspiration biopsy should be repeated, and, if the cytologic examination again shows no tumour cells, the case should be referred for surgical exploration.

Undifferentiated carcinomata. In the undifferentiated carcinomata, the cytologic picture was usually that of poorly differentiated or anaplastic carcinoma with a decrease in the cytoplasmic/nuclear ratio (Fig. 1 E). Six of these 15 carcinomata arose in pleomorphic adenoma. In four of the six cases, the aspiration-biopsy smears showed only carcinoma cells, and in the other two cases there were carcinoma cells and mesenchymal elements (Fig. 1 F).

VARIATIONS IN RADIOSENSITIVITY OF VARIOUS TYPES OF MALIGNANT SALIVARY-GLAND TUMOUR

P. A. Jakobsson and C. M. Eneroth

From Radiumhemmet and the Department of Otolaryngology Karolinska Hospital Stockholm Sweden

The radiosensitivity of five different types of malignant salivary gland tumour—adenoid cystic, acinic cell, muco-epidermoid, mucus-producing adenopapillary carcinoma and carcinoma in pleomorphic adenoma—has been studied on the basis of the criterion "palpable tumour which was not definitely palpable 6 weeks after the end of radiation therapy. In a series of 1678 cases of parotid tumour all patients who had received uniform radiation therapy were investigated.

In a retrospective study of parotid tumours in 1678 patients seen at Radiumhemmet, Stockholm from 1909 to 1958 the object was to analyse the radiosensitivity of malignant parotid tumours.

MATERIAL AND METHODS

A histological reclassification according to modern nomenclature (Eneroth, 1964) was made of all tumours. The prerequisites for a histological re-examination existed in all these 1678 cases, since slides and tissue blocks are filed at the Institute of Radiopathology Stockholm. After histological re-examination of the 1678 tumours, 299 were classified as malignant. Fifty-one patients with malignant parotid tumours who had received uniform pre-operative irradiation were investigated. Of these 51 patients, nine had adenoid cystic, 10 acinic cell, 19 muco-epidermoid nine mucus-producing adenopapillary carcinomata, and four carcinomata in pleomorphic adenoma.

If a tumour that was easily palpable at the first examination was not definitely palpable 6 weeks after the end of radiation therapy the

radiosensitivity was considered to be high. The pre-operative irradiation was given by short-distance techniques, either by using teleraedium units or ^{60}Co units with 6 to 7 cm between the radiation source and skin (Wakstam, 1965). One circular field, 6 cm in diameter was used. The dose maximum at 2 mm depth was calculated to be 2600 to 5000 rads. It was possible to calculate the dose at different depths throughout the tumour mass fairly accurately. The dose at 1, 2 and 3 cm depth was 2100-4300, 1600-3700, 1200-3500 rads, respectively.

RESULTS

In four of the nine cases of adenoid cystic carcinoma and in three of the 10 cases of acinic cell carcinoma, the tumour disappeared clinically in the course of 4 to 6 weeks after treat-

Table 1 The radiosensitivity of five different types of malignant salivary-gland tumours

	Radio-sensitive	Not Radio-sensitive	Total
Adenoid cystic carcinoma	4	5	9
Acinic-cell carcinoma	3	7	10
Muco-epidermoid carcinoma	0	19	19
Carcinoma in pleomorphic adenoma	0	4	4
Mucus-producing adenopapillary carcinoma	0	9	9

ment (Table 1) At subsequent operation mere ly small non-palpable residues were present. The other 12 cases of these two malignant parotid tumours presented evidence of only moderate or no regression after pre-operative irradiation. In none of the 19 cases of muco-epidermoid carcinoma, the four cases of carcinoma in pleomorphic adenoma and the nine cases of mucus-producing adenopapillary carcinoma did the tumour disappear clinically within 6 weeks, pre-operative irradiation producing only moderate or no regression.

DISCUSSION

Very little is known of the radiosensitivity of malignant salivary-gland tumours. In the present large series of patients with malignant parotid tumours who had received uniform radiation therapy there was a possibility of studying the radiosensitivity of malignant salivary-gland tumours.

According to estimates from a number of workers the radiosensitivity of adenoid cystic carcinomata varies widely (Ahlborn, 1935 Baclesse, 1946 Foote & Frazer, 1954 Berdal & Mylius, 1954 Blanck *et al* 1967) In this investigation adenoid cystic carcinoma appeared to be one of the more radiosensitive malignant parotid tumours. In four of the nine cases, the tumour disappeared clinically in the course of 6 weeks after treatment.

Some authors (Grafe *et al*, 1961 McCabe & Boles, 1962) have stated that acinic-cell carcinoma has low radiosensitivity others (Eneroth *et al* 1966) that there is a possibility of influencing this type of tumour by radiation therapy. In our series, acinic-cell carcinoma is close to adenoid cystic carcinoma in radiosensitivity. Three of 10 tumours showed marked radiosensitivity.

Most authors (Stewart *et al* 1945 Linell, 1948 Marcial-Rojas & Sommers, 1954 Paley 1965 Jakobson *et al*, 1968) state that muco-epidermoid carcinoma is of relatively low radiosensitivity. In none of the 19 muco-epidermoid carcinoma did the tumour disappear

clinically within 6 weeks after irradiation. Neither did the nine mucus-producing adenopapillary carcinomata, nor the four carcinomata in pleomorphic adenoma given pre-operative irradiation with the same technique show any radiosensitivity. This is in agreement with other authors (Eneroth *et al* 1968 Blanck *et al*, 1967).

No definite conclusions as to the radiosensitivity of these five different types of malignant salivary-gland tumours could be drawn from the present series, but adenoid cystic and acinic cell carcinomata seem to be the more radiosensitive types of malignant salivary-gland tumours.

In a retrospective study of parotid tumours in 1678 patients seen at Radiumhemmet Stockholm from 1909 to 1958 the object was to analyse the radiosensitivity of malignant parotid tumours.

MATERIAL AND METHODS

A histological reclassification according to modern nomenclature (Eneroth 1964) was made of all tumours. The prerequisites for a histological re-examination existed in all these 1678 cases, since slides and tissue blocks are filed at the Institute of Radiopathology Stockholm. After histological re-examination of the 1678 tumours, 299 were classified as malignant. Fifty-one patients with malignant parotid tumours who had received uniform pre-operative irradiation were investigated. Of these 51 patients, nine had adenoid cystic, 10 acinic cell, 19 muco-epidermoid, nine mucus-producing adenopapillary carcinomata, and four carcinomata in pleomorphic adenoma.

If a tumour that was easily palpable at the first examination was not definitely palpable 6 weeks after the end of radiation therapy the

radiosensitivity was considered to be high. The pre-operative irradiation was given by short-distance techniques, either by using telerradium units or ^{60}Co units with 6 to 7 cm between the radiation source and skin (Volkmann, 1965). One circular field, 6 cm in diameter was used. The dose maximum at 2 mm depth was calculated to be 2600 to 5000 rads. It was possible to calculate the dose at different depths throughout the tumour mass fairly accurately. The dose at 1, 2 and 3 cm depth was 2100-4300, 1600-3700, 1200-3500 rads, respectively.

RESULTS

In four of the nine cases of adenoid cystic carcinoma and in three of the 10 cases of acinic cell carcinoma the tumour disappeared clinically in the course of 4 to 6 weeks after treat-

Table 1 The radiosensitivity of five different types of malignant salivary-gland tumours.

	Radio-sensitive	Not Radio-sensitive	Total
Adenoid cystic carcinoma	4	5	9
Acinic-cell carcinoma	3	7	10

Carcinoma in pleomorphic adenoma	0	4	4
Mucus producing adenopapillary carcinoma	0	9	9

CYTOLOGICAL ASPIRATION BIOPSY IN OTORHINOLARYNGOLOGICAL PRACTICE

A PRELIMINARY REPORT WITH SPECIAL REFERENCE TO METHOD

A. Kotivunemi, E. Saksela and E. Holopainen

*From the Department of Otolaryngology and the Second and Third Departments of Pathology
University of Helsinki Finland*

The material consists of 128 lesions in the head and neck, 52 of which were salivary-gland lesions. A Millipore-filter technique was used in collecting cytological material. With this technique it is, on the other hand, possible to collect even very scanty amounts of cellular material, and, on the other preservation of cells and good staining properties are ensured. So far histological verification has been performed in 62 of these cases. As to malignancy false positive diagnoses were made in 2.3 per cent and false negative diagnoses in 5.5 per cent of the cases.

Studies on aspiration biopsy were performed as early as the 1930's (Martin & Ellis, 1930 1934) but as a diagnostic tool it was first used systematically by Swedish scientists in the 1950's. Mavec, Eneroth and others investigated aspiration biopsies of salivary gland (Mavec *et al.* 1964 Eneroth *et al.* 1965 1966 1967), Franzén and Esposti and their co-workers studied those of the prostate (Franzén *et al.* 1960 Esposti, 1960 Esposti *et al.* 1960) Einhorn & Franzén studied the thyroid gland (1962), Zajicek *et al.* (1967) the mammary gland, and Naselli (1967) studied lung tumours. In addition, Söderström published a comprehensive monograph on aspiration biopsy (1966). In the above-mentioned studies only—or primarily—the haematological method was used, i.e. the cytological smears were dried and stained according to the May-Grünwald-Giemsa method (with the exception of Naselli's study).

In the Second Department of Pathology at Helsinki University (and later also in the Central Laboratory of Pathology founded in 1967) cytological aspiration biopsies have been stud-

ied since 1959. First, samples were taken from lung tumours and then (since 1966) from the prostate, mammary gland, kidney pancreas and lymph nodes (data on these are to be published later). In otorhinolaryngological practice some aspiration biopsies were done in 1966 but systematic investigations were not performed until the beginning of 1968.

METHOD

The samples were taken with the instruments developed by Franzén, and the biopsy technique was the same as in the publications mentioned above. The cellular material was delivered from a syringe into a sample tube containing 5-10 ml of 50 per cent ethanol, with which the syringe and needle were also rinsed so as to remove the cellular material as carefully and thoroughly as possible. When the first sample was heavily contaminated with blood or seemed scanty a second sample was in some cases taken at once. The cellular material was allowed to remain in the fixative (50 per cent ethanol) for a few hours, whereafter the material was collected on to a Millipore filter. The filter was fixed and stained according to the Papanicolaou technique, specifically modified for Millipore filter. The apparatus consisted of an ordinary rectangular filter holder and rectangular filters (pore size 5 or 8 µ). When preparing specimens with scanty cellular material, the authors employed a special inner funnel of plastic, by means of which the cel-

CYTOLOGICAL ASPIRATION BIOPSY IN OTORHINOLARYNGOLOGICAL PRACTICE

A PRELIMINARY REPORT WITH SPECIAL REFERENCE TO METHOD

A. Koivumies, E. Saksela and E. Holopainen

*From the Department of Otolaryngology and the Second and Third Departments of Pathology
University of Helsinki, Finland*

The material consists of 128 lesions in the head and neck, 52 of which were salivary-gland lesions. A Millipore-filter technique was used in collecting cytological material. With this technique it is, on the other hand, possible to collect even very scanty amounts of cellular material, and, on the other, preservation of cells and good staining properties are ensured. So far histological verification has been performed in 62 of these cases. As to malignancy false positive diagnoses were made in 2.3 per cent and false negative diagnoses in 5.3 per cent of the cases.

Studies on aspiration biopsy were performed as early as the 1930's (Martin & Ellis, 1930 1934), but as a diagnostic tool it was first used systematically by Swedish scientists in the 1950's. Mävec, Eneroth and others investigated aspiration biopsies of salivary gland (Mävec *et al* 1964 Eneroth *et al* 1965 1966, 1967). Franzén and Esposti and their co-workers studied those of the prostate (Franzén *et al* 1960 Esposti, 1960 Esposti *et al*, 1960) Enhorn & Franzén studied the thyroid gland (1962) Zajicek *et al* (1967) the mammary gland, and Naselli (1967) studied lung tumours. In addition, Söderström published a comprehensive monograph on aspiration biopsy (1966) In the above mentioned studies only—or primarily—the haematological method was used, i.e. the cytological smears were dried and stained according to the May-Grünwald-Giemsa method (with the exception of Naselli's study)

In the Second Department of Pathology at Helsinki University (and later also in the Central Laboratory of Pathology founded in 1967) cytological aspiration biopsies have been stud-

ied since 1959 First, samples were taken from lung tumours and then (since 1966) from the prostate, mammary gland, kidney pancreas and lymph nodes (data on these are to be published later) In otorhinolaryngological practice some aspiration biopsies were done in 1966, but systematic investigations were not performed until the beginning of 1968

METHOD

The samples were taken with the instruments developed by Franzén, and the biopsy technique was the same as in the publications mentioned above The cellular material was delivered from a syringe into a sample tube containing 5-10 ml of 50 per cent ethanol, with which the syringe and needle were also rinsed so as to remove the cellular material as carefully and thoroughly as possible. When the first sample was heavily contaminated with blood or seemed scanty a second sample was in some cases taken at once. The cellular material was allowed to remain in the fixative (50 per cent ethanol) for a few hours, where after the material was collected on to a Millipore filter The filter was fixed and stained according to the Papanicolaou technique specifically modified for Millipore filter The apparatus consisted of an ordinary rectangular filter holder and rectangular filters (pore size 5 or 8 μ) When preparing specimens with scanty cellular material, the authors employed a special inner funnel of plastic, by means of which the cel-

lular material was concentrated to the centre of the filter over a round area, 12 mm in diameter so as to make the screening of these samples easier. The rectangular stained filters were mounted with Permount between the object and cover glass.

MATERIAL

The samples were collected in the routine work at Helsinki University ENT Clinic from various lesions in the head and cervical region, particularly when a tumour was suspected. By May 1969 we had samples from 128 cases, viz. from 52 salivary-gland lesions, 69 lesions in the cervical region (enlarged lymph nodes and other lesions) and seven other lesions in the mouth and pharynx. So far histological studies have been performed in 62 of the cases.

RESULTS

In 19 of the salivary-gland samples, the cytological findings indicated mixed tumour. Of these cases, 10 have been verified histologically. In the remaining nine cases a firm encapsulated tumour suspected to be mixed tumour was found in the clinical investigation. Two of the 10 cases investigated histologically were found to be malignant (infiltrative growth). One of these had already been found to be malignant in the cytological investigation, whereas the cellular picture of the other case was considered benign. In only one case of mixed tumour was the aspirated cellular material so poor that no diagnosis could be made cytologically.

In addition to mixed tumours, the salivary gland material contained four other tumours. Two were histologically verified adenoid cystic carcinomata. Both of them were also cytologically considered to be malignant; one had been classified properly in the cytological investigation, in the other case however anaplastic carcinoma had been suggested. The remaining two were acinic-cell tumours; one of them was malignant (cytological sample acellular) and

the other was the rare benign variant (cytologically acinic-cell tumour probably malignant).

Finally in one case, the cytological diagnosis was cystadenolymphoma, but the operation has not yet been undertaken, and so the case remains histologically unverified.

The remaining 27 salivary-gland samples were taken from benign non-neoplastic lesions. These lesions were also diagnosed to be benign cytologically except for one case of Mikulicz's disease, which was at first suspected to be a lymphoma, in a second aspiration biopsy a benign inflammation, and only histologically was the diagnosis of Mikulicz's disease established. For obvious reasons, the histological confirmation was performed only in nine of these benign lesions.

Of the lesions in the cervical region (69 cases) 57 were enlarged lymph nodes. On the basis of the cytological findings 23 were considered or suspected to be malignant (19 metastatic carcinoma, 4 lymphoma). All the metastatic carcinomata were verified histologically and so were two additional cases in which the cytological findings had been negative. In one case, the sample was acellular and in the other case the first sample was negative, while the control sample indicated malignancy. In addition to these two false negative diagnoses, there was one false positive cytological lymphoma diagnosis. Clinically this case was suspected to be malignant, but the histological biopsy showed only atypical hyperplasia.

Twenty-six lymph node samples were cytologically benign or inadequate (18 and 8 respectively). Ten of these were studied histologically and in the remaining 16 cases the lesion was considered to be benign on the basis of the clinical investigation.

Of the other lesions in the cervical region (12 cases) seven were histologically confirmed cysts, four of which had already been diagnosed on the basis of the cytological findings. In three cases, however the cytological samples had been completely acellular. Of the remaining five cases, four were both cytologically and histologically found to be benign thyroid

gland nodes. Finally one neurilemmoma had been cytologically diagnosed as benign mesenchymal tumour.

In seven cases, aspiration-biopsy samples were taken from the mouth or pharynx. In five cases, the cytological diagnoses were verified histologically: two malignant lympho-epitheliomas in the pharynx and three benign inflammatory lesions. In one of the two remaining cases the cytological sample showed malignancy in agreement with the clinical diagnosis. Histological verification is not yet available. In the seventh case, the lesion was found to be benign.

DISCUSSION

In our experience the Millipore technique is better than ordinary smear preparations when using the Papanicolaou staining method, because

- the cellular material is fixed immediately *in situ*, i.e. three-dimensionally which ensures excellent preservation of cells and facilitates comparison between cytologic and histologic preparations,
- cellular material does not remain in the syringe, as the syringe is rinsed with the fixative, which is not done in the smear technique,
- the drying of cellular material is efficiently avoided. The staining properties of dried smears are poor in the Papanicolaou technique, and so interpretation is made more difficult or even impossible
- material from several aspirations can be collected on the same filter and is consequently easier to study

So far our material is so limited that no definite conclusions can be drawn. A review of the results shows that satisfactory samples were obtained in 114 out of 128 cases (89 per cent): the acellular samples were rare in parotid cases (two out of 52, i.e. 4 per cent) and more common among cysta coli samples (three out of 12, i.e. 25 per cent). As no malignancy (false positive diagnoses) were made in three cases (2.3 per cent). These occurred at the beginning of this work when our knowledge of

cytological pictures of this kind of aspiration biopsies in Millipore technique was scanty. False negative diagnoses were made in seven cases (5.5 per cent). In three cases, the false negative diagnosis was due to an acellular sample. These results agree, on the whole, with the results found in the literature (e.g. Eneroth *et al* 1967).

A description of the morphology will be published later in connection with the results of a more comprehensive material.

DISCUSSION

H. Diamant What do you mean when you say Mikulicz's disease? I have for at least 10 years avoided this name and so has a lot of other people working in this field. I think that it has very little meaning and that it should be removed from our terminology.

E. Holopainen (Reply to Diamant) We have used this diagnosis in the clinical work as well as in histopathology. As long as the aetiology and the pathogenesis of these collagenous diseases are unknown, this diagnosis may be considered reasonable.

THE SIGNIFICANCE OF THE AUTONOMIC INNERVATION FOR THE SALIVARY SECRETION IN THE HUMAN PAROTID AND SUBMANDIBULAR GLANDS

K. A. Norberg, C. M. Eneroth and T. Hökfelt

From the Department of Histology, Karolinska Institute and the Departments of Anaesthesiology and Otolaryngology, Karolinska Hospital, Stockholm, Sweden

The distribution of sympathetic and parasympathetic nerves in human salivary glands has been studied histochemically and electron-microscopically. Both glands are innervated by sympathetic (noradrenaline-containing) and parasympathetic (cholinesterase-containing) nerves. The sympathetic nerve terminals may also be identified by their content of vesicles of special type. The morphological findings permit the conclusion that the adrenergic transmitter noradrenaline can probably reach all acinar cells as well as the myo-epithelial cells. A large proportion of the effector cells can evidently also be influenced directly by the parasympathetic transmitter acetylcholine.

Salivary secretion is impaired by surgical or pathological damage of the parasympathetic nerves innervating the salivary glands. Especially the chorda tympani, which contains the parasympathetic outflow to the submandibular gland, is open to injury by such conditions as surgery of the stapes, radical operation for chronic otitis, idiopathic facial nerve palsy and skull fractures.

It is obvious that salivary secretion is controlled by the autonomic nervous system, but the relative importance of the sympathetic and parasympathetic nerves has not been established. Thus, while the parasympathetic nerves evidently are the main secretory nerves, the importance of the sympathetic nervous system is obscure.

One way to start an elucidation of these problems is to study the distribution of parasympathetic and sympathetic nerves in the salivary glands. In the present investigation, three techniques were used to study the sympathetic innervation (fluorescence histochemistry ac-

cording to Falck, 1962 and Falck *et al.*, 1962) parasympathetic innervation (cholinesterase staining) and ultrastructure of the autonomic nerves (electron microscopy using potassium permanganate according to Richardson, 1966). A full account of this investigation with the three techniques has been given by Eneroth *et al.* (1969).

Fluorescence microscopy revealed a rich network of sympathetic nerve terminals enclosing the acini of both submandibular and parotid glands. Cholinesterase staining resulted in a similar picture, a network of parasympathetic nerve terminals enclosing the acini.

The electron-microscopic studies permitted selective identification of sympathetic and parasympathetic nerves, the former containing dense cored (noradrenaline-containing) granules with a diameter of about 500 Å. Both sympathetic and parasympathetic nerves were found mostly to run in the same Schwann cells, and thus probably reach the same effector cells. This observation supports the view that the acini of the salivary glands are doubly innervated by both the sympathetic and the parasympathetic nervous system.

The abundant occurrence of both sympathetic and parasympathetic nerve terminals innervating the acinar cells strongly indicates that both types are of functional importance. In the light of these results and functional observations in other mammals, it seems highly probable that the sympathetic nerves can also induce salivary secretion. Thus, it is probable that the

HORMONAL SIALOSIS DURING TWO CONSECUTIVE PREGNANCIES

J Udsen and K. A. Thomsen

From the Department of Otolaryngology the University Hospital Copenhagen, Denmark

During her first pregnancy a 17-year-old woman revealed distinct bilateral swelling of the parotid glands. The swelling was believed to be of hormonal origin and subsided spontaneously after delivery. During her next pregnancy a year later a similar swelling occurred.

A woman, aged 17, was examined in April 1967 a few days after her first delivery. At this time there was distinct swelling of the parotid glands. Palpation revealed that the glands were firm, homogeneous and indolent.

In March 1967 the patient had been examined in a local hospital, because of bilateral swelling of the parotids, which had begun in the first trimester of her pregnancy. Her complaints were only of a cosmetic nature; specifically there was no oral dryness or salivation. Serological tests (differential count, haemoglobin, sedimentation reaction, MCV, MCHV, leukocytes, eosinophils, platelets, electrophoresis) showed no abnormalities. An examination by the internist was arranged, but the patient did not come.

In our department, all the blood tests were repeated, and AGKT, ANF, LE cells, AST and serum amylase were also analysed. All tests as well as chest radiography showed normal conditions. Sialography of the parotid glands was planned, but again the patient failed to attend.

The patient was examined again shortly after her second delivery in March 1968 and again pronounced bilateral swelling of the parotids was present. The patient informed us that the swelling had subsided quickly after the first delivery and that the glands became perfectly normal for a few months until the first trimester of her second pregnancy when bilateral swelling of the parotid region reappeared. She had no other complaints.

As the literature gives only a few examples of this disease, we find that this case may be of interest.

remaining secretion which is found after damage of the parasympathetic nerves is caused largely by sympathetic nervous activity and not by endocrine factors.

DIPHASIC IMPEDANCE CHANGE AND ITS APPLICABILITY IN CLINICAL WORK

G Flottorp and G Djupesland

*From the Department of Otolaryngology and the Institute of Audiology Rikshospitalet,
Oslo Norway*

In 186 ears of 115 patients, impedance changes at the onset and at the end of the stimulus ("diphasic impedance changes") were recorded, using Madsen Impedance Instruments Model ZO 61 and Model ZO 70. The eliciting stimuli were:

1. Tactile stimulus
2. Acoustic stimulus
3. Defensive-reaction or startle-evoking stimulus

In some cases, all three stimuli evoked diphasic impedance changes. In most cases, however, only stimuli 2 and 3 or stimulus 3 alone, produced such changes. A combination of monophasic and diphasic impedance change was never observed in one and the same ear. Diphasic impedance change was always found to represent two successive, transitory reductions of the middle-ear impedance. Based upon the observed pattern of the impedance change it is suggested that the change is caused by a special type of movement of the ossicular chain, found in ears with otosclerosis. The more advanced the state of otosclerosis, the more vigorous is the stimulus necessary to elicit the diphasic change. We have found this pattern of impedance change useful as a diagnostic aid.

At the VII International Congress of Audiology in Copenhagen, 1964, Terkildsen (1964) stated the following regarding impedance changes elicited by middle-ear muscle activity:

"As a rule, the intratympanic muscle reflexes are absent in patients with otosclerosis. In rare cases, there may be a muscle response, but only as a momentary burst at the onset of sound and again when the sound is turned off. This on-off reflex can only be caused by the tensor muscle." At the same Congress (1964) we presented a few cases in which a similar on-off phenomenon had been observed, hereafter called "diphasic impedance change". We have since continued our study looking for pa-

tients in whom a diphasic impedance change could be elicited.

MATERIAL AND METHOD

From 1962 to 1969 we found diphasic impedance change in 186 ears of 115 patients. Table 1 shows the distribution of the material of which 63 per cent were females. 83 per cent were between the ages of 30 and 59 years. The diagnosis was based on the history, clinical examination of the ear, nose and throat, and audiological findings. Of the patients, 112 suffered from otosclerosis. The diagnosis was verified by surgery in 59 cases. In six of these cases, otosclerotic foci were found by histological examination of the removed stapes plate. In addition to otosclerotic findings, two patients exhibited osteogenesis imperfecta (blue sclerae,

one ear operated) and one exhibited a typical Cogan's syndrome.

The impedance changes were recorded by a modified Madsen Acoustic Impedance Meter Model ZO 61. This apparatus has previously been described by Djupesland (1967). In addition, the Madsen Electro-Acoustic Impedance Bridge, Model ZO 70 was employed for the last 30 patients. Both ears of each patient were examined. In approximately half of the patients, impedance changes were recorded on a Brüel and Kjær Level Recorder (2405 A) using a linear potentiometer. Movement of the indicator needle on these impedance instruments also provided an easy observation of the form of the impedance change.

Impedance changes were investigated with the use of the three main types of stimulus regularly applied to patients in our clinic:

1. Tactile stimulus, ipsilateral and contralateral, touching the skin around the opening of the external auditory meatus with a piece of cotton wool.

2. Acoustic stimulus, using Bárány's noise box and pure tones.
3. Defensive-reaction or startle-evoking stimulus, consisting of a sudden strong lifting of the upper eyelids. The thumbs of the examiner resting lightly against the lids, are pressed suddenly upward and inward.

The impedance changes were correlated with the type and degree of hearing loss in order to give the study clinical applicability.

RESULTS

The pattern of the impedance change (Fig. 1) served to divide our results into two main groups (Fig. 2.)

1. Normal, monophasic impedance change.
2. Abnormal, diphasic impedance change.

IMPEDANCE CHANGE	STIMULUS	IMPEDANCE CHANGE	PERCENT OF ALL PATIENTS

Fig. 2. Distribution of response patterns recorded in the 230 ears examined.

(In some cases, we saw the first phase being split up (Fig. 3 d.) thereby producing a virtually triphasic pattern, however we counted these as diphasic in the sense that they are different from the monophasic type.)

The most remarkable result is probably that we never found a combination of monophasic reaction to one stimulus and a diphasic pattern to another in one and the same ear. In other words, a diphasic pattern may be seen in combination with no change, but never together with a monophasic change.

The diphasic impedance change may present itself in various patterns:

DIPHASIC IMPEDANCE CHANGE AND ITS APPLICABILITY IN CLINICAL WORK

G Flottorp and G Djupesland

*From the Department of Otolaryngology and the Institute of Audiology Rikshospitalet
Oslo Norway*

In 186 ears of 115 patients, impedance changes at the onset and at the end of the stimulus ("diphase impedance changes") were recorded, using Madsen Impedance Instruments Model ZO 61 and Model ZO 70. The eliciting stimuli were:

- 1 Tactile stimulus
- 2 Acoustic stimulus
- 3 Defensive-reaction or startle-evoking stimulus

In some cases, all three stimuli evoked diphase impedance changes. In most cases, however, only stimuli 2 and 3 or stimulus 3 alone, produced such changes. A combination of monophasic and diphase impedance change was never observed in one and the same ear. Diphase impedance change was always found to represent two successive, transitory reductions of the middle-ear impedance. Based upon the observed pattern of the impedance change it is suggested that the change is caused by a special type of movement of the ossicular chain, found in ears with otosclerosis. The more advanced the state of otosclerosis, the more vigorous is the stimulus necessary to elicit the diphase change. We have found this pattern of impedance change useful as a diagnostic aid.

At the VII International Congress of Audiology in Copenhagen 1964 Terkildsen (1964) stated the following regarding impedance changes elicited by middle-ear muscle activity: "As a rule, the intra-aural muscle reflexes are absent in patients with otosclerosis. In rare cases, there may be a muscle response but only as a momentary burst at the onset of sound and again when the sound is turned off. This on-off reflex can only be caused by the tensor muscle." At the same Congress (1964) we presented a few cases in which a similar on-off phenomenon had been observed hereafter called "diphase impedance change". We have since continued our study looking for pa-

tients in whom a diphase impedance change could be elicited.

MATERIAL AND METHOD

From 1962 to 1969 we found diphase impedance change in 186 ears of 115 patients. Table 1 shows the distribution of the material of which 63 per cent were females. 83 per cent were between the ages of 30 and 59 years. The diagnosis was based on the history, clinical examination of the ear, nose and throat, and audiological findings. Of the patients, 112 suffered from otosclerosis. effect) and a larger change at the end of the stimulus (large off-effect) (Fig. 3 c)

A split impedance change at the beginning (split on-effect) together with a normally shaped, but smaller change at the end (small off-effect) (Fig. 3 d) This pattern was rarely seen.

By means of the Madsen Electro-Acoustic impedance Bridge, Model ZO 70 it was possible to determine the direction of the impedance change. In normal ears, with normal middle ear pressure we always observed that the monophasic impedance change represents a momentary increase of the impedance (higher acoustic ohm, less compliance) The diphasic impedance change however always consists of two components of decreased impedance separated in time by a value being either normal or increased. We were unable to examine the direction of the impedance change in all patients, since the impedance bridge ZO 70 was available only during the last part of this study. However so far there has been no exception from the mentioned pattern.

Some of our patients were able to observe a momentary loudness increase of the low-frequency probe tone in conjunction with the diphasic pattern. In cases of monophasic impedance change, many of our patients observed a decrease in loudness. However most patients seem to be unable to observe any loudness change at all in connection with an elicited impedance change.

In patients having had a successful stapedectomy diphasic impedance changes were elicited, but only by lifting the upper eyelids.

If we try to correlate the pattern of impedance change with the degree of hearing loss in the examined ear it is found that diphasic change for all three stimuli is only seen in patients with negligible hearing loss in that ear. In the other ear of these patients we always found a greater hearing loss of the otosclerotic type. As the hearing loss increases first the reaction to the tactile stimulus disappears then the acoustically elicited diphasic changes van-

ish. Only in very rare cases was it impossible to elicit diphasic impedance change by lifting the upper eyelids. Today we have some doubt as to whether it should not be possible to elicit impedance changes also in these cases when the stimulus is properly applied.

DISCUSSION AND CONCLUSIONS

Without trying to explain the mechanism responsible for the diphasic pattern, we think our results indicate that the observed pattern is caused by a special type of movement of the ossicular chain, due to action of either the stapedius muscle or the tensor tympani muscle or both muscles in co-operation. It can hardly be due to any artefacts in the measuring instrument itself caused by a variation of the impedance vector being transformed by the instrument to a variation on a linear scale. Since a diphasic impedance change is seen in operated ears in which the tendon of the stapedius muscle has been cut, the tensor muscle solely must be able to produce the special movement of the chain. On the other hand, the fact that tactile stimulation of the meatus (known to activate only the stapedius muscle Djupesland, 1967) is able to elicit the diphasic pattern indicates that the stapedius muscle must also be able to perform the action producing the diphasic change. The diphasic pattern may be produced as a result of an inward movement of the tympanic membrane together with a change in the shape of the tympanic membrane. Such a movement might increase temporarily the volume in the ear canal without increasing the stiffness of the eardrum and the ossicular chain, resulting in the very special impedance values seen at the onset and at the end of the stimulus. However it seems more likely that the ossicular chain itself is temporarily in a condition producing greater conductivity for the vibrations (smaller impedance value) at the onset of the stimulus and at the end of the stimulus. This may be comparable to Klockhoff's finding (1961) that most tensor responses in genuine stapes ankylosis are as-

Fig. 3 Various patterns of the diphasic impedance change

- Great change at the beginning, small change at the end of the stimulus.
- Almost equal changes at the beginning and end of the stimulus.
- Small change at the beginning, greater change at the end of the stimulus.
- Split change at the beginning, normal change at the end of the stimulus (only seen for tactile and acoustic stimuli).

IMPEDANCE MEASUREMENTS

PROBE TONE INTENSITY AND MIDDLE EAR REFLEXES

K. Terkildsen, P. Osterhammel and S. Scott Nielsen

From the Audiological Laboratory Department of Otolaryngology University of Copenhagen Denmark

Eleven normal subjects were examined by the impedance method with respect to the influence of probe tone intensity on the middle ear muscle reflexes. If the probe tone is reduced from 70 dB sensation level to 60 dB SL, the threshold tends to become higher and the reflexes are smaller. This holds for reflex eliciting stimuli up to around 95-100 dB. With stronger stimuli, the reflexes become stronger with weak probe tones. Thus, exact knowledge about probe-tone intensity is important for accurate evaluation of the middle-ear muscle reflexes by the impedance method.

It is well known that the middle-ear muscles in man can be activated in several ways.

The acoustic reflexes involve only few synapses, and they might be designated as a primary type of response, in contrast to reflexes that are induced by tactile stimulation or as part of particular activity patterns in muscles of the head or the neck. Furthermore there is no doubt that other conditions, such as mental activity previous experience with intense listening, noise exposure and emotional attitude are of some importance. All these factors interact mutually in a complex manner that can best be described in terms of habituation or facilitation.

When the middle-ear muscle reflexes are measured by means of the impedance method, the so-called indicator ear is submitted to tactile stimulation from the insert tip and at the same time to an acoustic stimulus by the probe tone. The tactile sensation will elicit a contraction which vanishes within seconds through habituation. The probe tone is of an intensity which is considerably below the reflex threshold at this frequency. With the knowledge we

have about mutual facilitation or blocking of the habituation process, when several modes of stimulation are applied at the same time, even if they are at a subliminal level, it is of interest to see what influence the probe-tone intensity may have on the reflexes.

The Madsen ZO-70 impedance apparatus is well suited for such an investigation. The probe-tone intensity at the ear-drum is always the same, when the cursor scale has been adjusted to obtain a zero balance. Due to the measuring principle, there is a linear relation between changes of the ear-drum impedance and the magnitude of deflection which is measured by means of the apparatus. In the commercial apparatus, the probe-tone intensity is 65 dB SL. We had a model adapted, so that it was possible to choose between two probe-tone intensities, 60 dB and 70 dB. A single switch sufficed to shift the intensity. It was ascertained through measurements that the linear characteristics remained unchanged with both intensities. At 220 cps, 70 dB SL is still 10-15 dB below the reflex threshold. During the investigation we found no reason to suspect that this did not hold true, and there was no indication of a reflex when the probe tone was shifted from weak to strong. The reflexes were recorded by means of a Mingograph 81.

It was decided to use the frequencies 250 and 1000 cps as reflex-eliciting stimuli in the contralateral ear. Each tone was presented automatically with a duration of 5 sec, rise-decay time 25 msec, and intervals between 15-20 sec.

sociated with a transient impedance decrease

However at the present time it is of greater interest to examine the correlation between the diphasic impedance change and the type of hearing loss present. Since we have so far seen diphasic impedance changes only in connection with otosclerotic ears, or ears that may probably be compared mechanically with otosclerosis (no movement of the stapes foot plate, either caused by fixation or by defective crura) it is likely that this special impedance pattern is pathognomonic of otosclerosis. It has been found at all stages of hearing loss resulting from otosclerosis, the pattern of the elicited impedance change being the same. However the possibility of eliciting it varies with the degree of hearing loss. In more advanced stages, the diphasic impedance change can be elicited only by means of the rather strong stimulus that leads to the defensive reaction i.e. vigorous lifting of the upper eyelids.

We have found this impedance pattern valuable in identifying otosclerosis in its earliest stages. Especially in cases in which the size of the air bone gap is so small that it is in reality doubtful or in which otosclerosis is combined with a sensory neural hearing loss, we have found it useful to have this objective registration to solve differential diagnosis problems.

DISCUSSION

G Lidén. We consider the acoustic middle-ear reflex test very useful in separating conductive lesions from sensorineural impairment. We have observed "responses" in some cases with otosclerosis, but these were due to interactions between stimulus tone and probe tone.

G Flottorp (Reply to Lidén). Diphasic impedance changes have been elicited in otosclerotic ears at stimulus intensities varying with the hearing loss present. In cases with normal and near normal hearing in the stimulated ear we have elicited diphasic impedance changes at normal impedance threshold i.e. at sound-pressure levels from 80–90 dB. It should probably be emphasized that we have always seen diphasic impedance changes represent a transitory decrease in the impedance, while the normal monophasic changes have always been a transitory increase in the impedance.

Graphs showing of compliance with different probe-tone intensity

Fig. 3.

weak probe tone are smaller up to a stimulus intensity of 95–100 dB, and above this level they are larger. The difference is statistically significant for stimulus levels 90 dB and 105, 110 and 115 dB.

It is evident that a statistical evaluation for the low stimulus intensities loses its meaning simply because there are so few results. Nevertheless the probe-tone intensity appears to have its largest influence just here.

Our results show that the probe-tone intensity is important when the middle-ear muscle reflexes are evaluated by means of the impedance method, both with regard to the reflex threshold and the magnitude of the reflexes above the threshold. Near the threshold the probe tone appears to facilitate the reflex in spite of the fact that its intensity is considerably below the reflex threshold. It is difficult

to explain why the reflexes at high stimulus intensities are stronger with a weak probe tone. It might be assumed that the strong probe tone would cause an increase of muscle tonus and in this way reduce the phasic response during a reflex. This explanation seems unlikely if it is remembered that the procedure involved very frequent shifts of probe-tone intensity and that these shifts caused no change in the stationary ear-drum compliance whatever. Maybe we are concerned with some kind of habituation to strong tones, but at the present time this question must be left open.

DISCUSSION

G. Salomon. Interaction between different types of stimulation of the middle ear muscles has also been demonstrated in cats (Salomon, G. 1966. Middle ear muscle activity *Proc Royal Soc* 59 966). As in your experiments, facilitation and inhibition were present, depending on a variety of parallel stimuli. It may be appropriate to think of the middle-ear muscle reflex as guided by a sum of input stimuli, the power of each stimulus depending on the state of the CNS, and the habitual pattern of reflex of each person.

I think that when Lidén found only tensor activity in response to sound in 20% we must assume that in the other patients, although no tensor response to sound was demonstrated, an influence on the tensor mechanism must have taken place.

The registration was started at the reflex threshold for both frequencies with both probe tone intensities, and during the procedure there would be a continual shifting between the two probe-tone intensities and frequencies. Maximum intensity for 250 cps was 105 dB and for 1000 cps 120 dB. Each reflex represents the average of three consecutive measurements.

The middle-ear pressure was measured before each test period and found to be between zero and -1 cm water pressure in all the subjects. During the test the ear-canal pressure was kept at atmospheric level. Furthermore the ear-drum compliance was measured in the usual way as the difference between the values obtained with pressure gradients of zero and +200 mm water pressure, respectively.

At the end of the examination the maximal reflex was measured in absolute terms. After balancing the bridge, a 120 dB 1000 cps tone was applied to the other ear. During the reflex contraction a new balance was obtained. The difference between those two values gives the compliance reduction during the reflex directly and due to the linearity of the registration it permits a calculation in absolute terms of all reflexes recorded in the same session.

Eleven normal persons were test subjects, six male and five females, age range 19-45 years with an average of 31 years. It is our experience that persons employed in acoustic professions often exhibit reflexes to rather weak stimuli, and all the test subjects were naive

Absolute change of compliance with increasing reflexes 1000 cps

Fig. 2.

with regard to such work. None were known to have been exposed to noise at traumatic levels. Only the right ear was examined in each subject.

Figs 1 and 2 show the reflexes for all 11 subjects. The reflex magnitude is given as the shift of ear-drum compliance in absolute values. Each point in the individual curve is an average of the results obtained with both weak and strong probe tones. The reflex elicited by a 1000 cps tone shows large individual differences with regard to both the threshold, the way it increases and the maximum value. For 250 cps it appears as if ears that exhibit a large change of compliance also tend to have a low reflex threshold.

The average ear-drum compliance for all subjects was 0.61 cc with variations from 0.44 to 0.79 cc. The shift of compliance during a maximal reflex averaged 0.23 cc, with variations from 0.1 to 0.42 cc. It might have been expected that subjects with a large ear-drum compliance would also exhibit large shifts during a reflex. There is such a tendency but it is not without exceptions. The person with the smallest reflex thus had an ear-drum compliance of 0.62 cc. There is also a tendency for patients with large ear drum compliance to have a reflex threshold at 250 cps that is lower than at 1000 cps.

Fig. 3 shows the average curves for all subjects at 1000 cps with weak and with strong probe tones, respectively. The reflexes with the

Absolute change of compliance with increasing reflexes 250 cps

Fig. 1.

the tympanic membrane in man is about as likely to suggest dominance of either the tensor tympani or stapedius muscle. However he pointed out that reversed manometric reflex reactions indicating a switch from negative pressure change to positive pressure change may be observed in some individuals. The reflex reversals may indicate predominant response of the other muscle or may be attributed to changed biophysical force vectors associated with the ossicular articulation. Further more, different patterns of cochlear stimulation may elicit variations in the responses of the two middle-ear muscles. Interfering bone conducted sound from the stimulated ear to the recorded ear might change the geometrical relationships of the stapes footplate and the ossicular joints and affect the instantaneous movements of the tympanic membrane accordingly.

Tactile stimulation with an air-jet directed towards the orbital region homolateral to the ear from which reflexes are recorded is known to elicit a contraction of both muscles. This was predicted by Klockhoff in 1961 and subsequently verified upon surgery of the middle ear (Lindström & Lidén, 1964; Djupealand, 1967). Another technique which is considered to be a reliable method for eliciting the stapedial muscle reflex is touching the skin on the anterior part of the auricle of the homolateral ear with cotton wool (Djupealand, 1968).

Even though several techniques are used for eliciting the intra-aural muscle reflex and numerous studies have been reported, the behaviour of the middle-ear muscles to acoustic stimulation still remains somewhat of a mystery. On the other hand, it is possible that measurements of relative impedance changes at the eardrum and eardrum movements can supplement each other and may provide more complete information as to the behaviour of the middle-ear muscles than if each dimension is evaluated separately. For this reason, both methods were combined to obtain a simultaneous measurement. Thus, we shall report the results of simultaneously recording the relative imped-

ance changes at the eardrum and eardrum movements during acoustic and non-acoustic stimulation. The purpose of this investigation was three-fold.

1. To clarify how the tensor muscle response appears in cases where the tensor is the only functioning muscle in the middle ear.
2. to study the pattern of the intra-aural reflex during combined acoustic and orbital air jet stimulation and,
3. to determine if the tensor tympani muscle reflex can be elicited by acoustic stimulation, and if so to what extent.

EQUIPMENT

The equipment used in this investigation has been described in detail elsewhere (1969). Therefore only a brief description will be given here. The apparatus consists of four main parts (Fig. 1) the intra-aural reflex indicator a pressure-transducer system for extratympanic manometry a unit for changing and monitoring the air pressure in the ear canal for tympanometry and a four-channel graphic recorder. Attached to a headband is a small metal case containing a receiver (miniature earphone) and a microphone. A two-pronged probe connected to these with rubber tubing is held in an airtight position in the ear canal by a soft foam-plastic cuff and a flexible locking arm described by Möller (1958). The probe tone has a fixed frequency of 800 Hz. The microphone monitors the sound pressure level of the probe tone in the ear canal between the tympanic membrane and the cuff.

Intra-aural reflex indicator The reflex indicator consists of two electronic bridges. On its panel there are three indicating meters. The first meter monitors the sound-pressure level of the probe tone. Immediately prior to making a reflex measurement, the level of the probe tone is adjusted to 70 dB SPL on this meter. In order to observe small changes in amplitude of the probe tone the second meter is connected to a DC-bridge permitting responses in either

SIMULTANEOUS RECORDING OF CHANGES IN RELATIVE IMPEDANCE AND AIR PRESSURE DURING ACOUSTIC AND NON ACOUSTIC ELICITATION OF THE MIDDLE EAR REFLEXES

G Lkén J L. Peterson and E. R. Harford

*From the Departments of Audiology Sahlgren's Hospital Göteborg Sweden
Louisiana State University School of Medicine New Orleans, Louisiana
and Northwestern University Evanston Ill U S A*

Intra-aural reflex responses for normal and pathological human ears were obtained while utilizing equipment constructed at Sahlgren's Hospital. Acoustic and tactile stimuli were employed to elicit reflexes. Responses were displayed simultaneously on two channels of a graphic recorder indicating changes in amplitude and amplitude phase of an 800 Hz probe tone in the recorded ear. Changes in air pressure in the same sealed auditory canal in response to middle ear muscle contraction were simultaneously recorded on a third channel. The response pattern on the impedance indicator and on the pressure transducer system during acoustic stimulation are primarily due to the stapedial muscle reflex. In a small fraction of the group of normal subjects (13 %) it appears that contraction of both middle-ear muscles was elicited by acoustic stimulation. In the group in which the tensor muscle was the only functioning muscle in the middle ear the tensor reflex could not be elicited by acoustic stimulation.

The elicitation of the stapedial and tensor tympani muscle reflexes by acoustic stimulation remains a controversial subject. It is generally agreed that in animals both muscles perform reflex contractions on acoustic stimulation. It is intriguing that this does not also hold unequivocally in man.

Interpretation of middle-ear muscle activity is related to the method used for measurement. For example using either absolute or relative measurements for the acoustic impedance at the tympanic membrane it is possible to ascertain the presence of intra-aural muscle reflexes (Metz, 1946). However complete abolition of reflex responses was noted in patients with suprapedial facial nerve lesions (Jepsen, 1955; Klockhoff 1961). In patients with paralysis of the trigeminal nerve, on the other

hand the responses to acoustic stimulation were preserved (Metz, 1946; Lindström & Lkén, 1964). A conclusion to be drawn from these investigations is that during acoustic stimulation the stapedius muscle is the sole cause of the so-called intra-aural muscle reflexes in man at least as far as these can be ascertained through impedance measurements.

Another measuring method for studying the effect of acoustic stimulation on the middle-ear reflexes is to determine the movement of the tympanic membrane (extratympanic manometry). Assuming that the intra-aural muscles are acting antagonistically the tensor muscle pulls the eardrum inward while the stapedius muscle may cause movements in both directions, but mostly outward. If the external ear canal is sealed air tight, movement of the eardrum results in measurable changes in the air pressure within the canal. Using different types of manometer systems, Mangold & Eckstein (1913), Terkildsen (1956, 1957, 1960), Mendelson (1957, 1966), Holst *et al* (1963) and Weiss *et al* (1963) claimed to demonstrate contractions in the tensor tympani muscle during acoustic stimulation. Holst *et al* (1963) concluded that the middle-ear muscle reflex is due to simultaneous contraction of both muscles. Terkildsen (1960) was more cautious and considered a definite action of the tensor muscle to be present on acoustic stimulation in only 62 % of the 60 human ears he examined. According to Mendelson (1966) the manometric direction of the reflex displacements of

series of tone burst for each frequency. The system was calibrated in hearing level re: 1964 ISO standard reference. The tones were presented through a TDH 39 telephonic earphone and had a maximum hearing level of 120 dB. However the maximum hearing level employed for most cases was limited to 110 dB.

Air-jet stimulation of the orbital region on the homolateral side of the recorded ear was performed according to Klockhoff & Anderson (1960). Tactile stimulation, according to Klockhoff (1961) and Djupesland (1964), was performed with a twist of cotton wool on a stick in the homolateral concha and in front of the homolateral tragus, care being exercised to avoid touching the probe.

INTRA AURAL REFLEX RESPONSES

Responses on the amplitude balance meter A and on the amplitude and phase balance meter AP" and on the extratympanic manometer "P" were recorded simultaneously during the presentation of stimuli.

According to Møller (1964) the middle-ear muscles act synergistically as far as impedance is concerned. That could imply an increase in the magnitude of the response in channel A when both muscles are contracting simultaneously. However Figs 2 b and 2 c show the response to air-jet stimulation for two normal ears in which both muscles are assumed to be functioning, and yet the magnitude of the response is less than in Fig. 2 a, which represents the response of an ear homolateral to supra-stapedial facial palsy with only a functioning tensor muscle. This means that the reflex indicator does not accurately measure the relative impedance change, but instead the change in SPL of the probe tone in the ear canal. Thus, the change of SPL in the ear canal does not appear to be proportional to change of impedance. Depending on the stimulus frequency and the resonance characteristics of the particular middle ear under study channel A" may show either negative or positive deflections.

The amplitude and phase of the probe tone

are balanced to zero in the AC-bridge. Consequently the deflections in this channel ("AP") are only positive.

The response P" indicates the movement of the tympanic membrane. This response is of special interest considering the fact that the tensor muscle presumably pulls the eardrum inward. As this movement occurs, the volume between the probe in the ear canal and the tympanic membrane will suddenly increase and the air pressure will decrease. This situation will appear as a relatively large spike-like negative or downward deflection on the P" channel of the recorder. An upward or positive deflection on the record indicates an outward movement of the eardrum. This response pattern, unlike the negative downward deflection, is usually a slower shallow broader response and is considered to show stapedial muscle activity. We have also observed negative deflections of the same type, which we have interpreted as stapedial muscle contractions according to Mendelson's findings (1966). Therefore, whenever we observed a sudden spike-like negative deflection in the P" channel we always interpreted this pattern to show tensor muscle contraction. When the response was either negative or positive, but the pattern broad and shallow we interpreted this to show stapedial muscle contraction.

Subjects

Two groups of subjects were used for this investigation. One group was selected on the basis of pathology which presumably precludes a stapedial muscle reflex. The other group consisted of persons with normal hearing and otologically normal middle ears.

The pathological group contained the following subjects.

- Supra-stapedial facial palsy with otologically-normal middle ears (N = 14)
- Unilateral footplate otosclerosis with normal opposite ear (N = 13)
- Bilateral footplate otosclerosis with one ear a post-operative stapedectomy (N = 12)

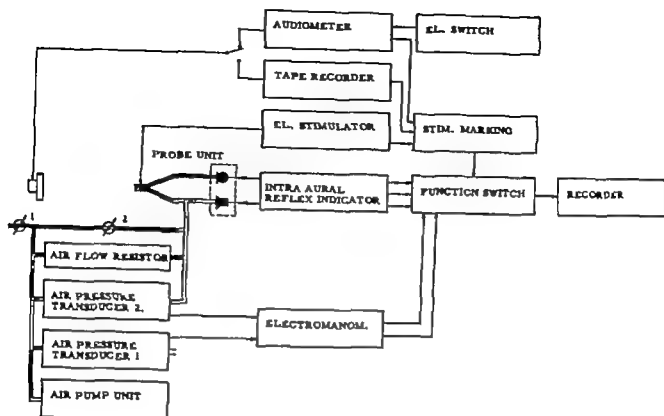

Fig. 1 Block diagram of the equipment.

a positive (upward) or negative (downward) direction. For the same purpose the *amplitude and phase* of the probe tone are balanced to zero in an AC bridge and connected to the third meter. This bridge permits responses only in a positive (upward) direction. The capacity to balance *amplitude* as well as *amplitude and phase* was originally made in order to discover which of the two bridges offers the most easily interpreted responses. It should be mentioned that the two bridges provide responses of different magnitude. The output from the second and third meters is recorded on the first two channels of a four-channel recorder (Mingograf type 34 Elema-Schönander).

Before the reflex measurements are made the middle-ear pressure is always checked by tympanometry. The reason for this is that either abnormal positive or negative pressure may suppress the elicitation of the middle-ear reflexes. The equipment and procedure for tympanometry is described in this issue (Lidén *et al* 1969).

Extratympanic manometry The change in air pressure produced by movements of the tympanic membrane is measured by a pressure transducer and an electromanometer (Elema-Schönander Type EMT 32 and EM 31) and fed to the third channel of the recorder. The highest sensitivity of the transducer corresponds to a change of ± 0.5 mm water pressure. In order to automatically balance the sensitive pressure transducer for changes in the static pressure in the ear canal an air flow resistor is provided with a time delay of 10 seconds.

Stimulation Pure tones corresponding to five different frequencies (250 500 1000 2000 and 4000 Hz) were recorded on magnetic tape with an intensity range of 40 dB in 2.5 dB discrete steps. The on and off times were one and two seconds, respectively. The rise and decay times were both 25 msec. The signals from the tape recorder were fed through an attenuator system which permitted the preselection of the maximum output for a given

series of tone burst for each frequency. The system was calibrated in hearing level re: 1964 ISO standard reference. The tones were presented through a TDH 39 telephonic earphone and had a maximum hearing level of 120 dB. However the maximum hearing level employed for most cases was limited to 110 dB.

Air-jet stimulation of the orbital region on the homolateral side of the recorded ear was performed according to Klockhoff & Anderson (1960). Tactile stimulation, according to Klockhoff (1961) and Djupesland (1964) was performed with a twist of cotton wool on a stick in the homolateral concha and in front of the homolateral tragus, care being exercised to avoid touching the probe.

INTRA AURAL REFLEX RESPONSES

Responses on the amplitude balance meter A and on the amplitude and phase balance meter AP and on the extratympanic manometer "P" were recorded simultaneously during the presentation of stimuli.

According to Møller (1964), the middle-ear muscles act synergistically as far as impedance is concerned. That could imply an increase in the magnitude of the response in channel A when both muscles are contracting simultaneously. However Figs. 2 b and 2 c show the response to air-jet stimulation for two normal ears in which both muscles are assumed to be functioning, and yet the magnitude of the response is less than in Fig. 2 a, which represents the response of an ear homolateral to supra-stapedial facial palsy with only a functioning tensor muscle. This means that the reflex indicator does not accurately measure the relative impedance change, but instead the change in SPL of the probe tone in the ear canal. Thus, the change of SPL in the ear canal does not appear to be proportional to change of impedance. Depending on the stimulus frequency and the resonance characteristics of the particular middle ear under study channel A may show either negative or positive deflections.

The amplitude and phase of the probe tone

are balanced to zero in the AC-bridge. Consequently the deflections in this channel ("AP") are only positive.

The response "P" indicates the movement of the tympanic membrane. This response is of special interest considering the fact that the tensor muscle presumably pulls the eardrum inward. As this movement occurs, the volume between the probe in the ear canal and the tympanic membrane will suddenly increase and the air pressure will decrease. This situation will appear as a relatively large spike like negative or downward deflection on the "P" channel of the recorder. An upward or positive deflection on the record indicates an outward movement of the eardrum. This response pattern, unlike the negative downward deflection, is usually a slower shallow broader response and is considered to show stapedial muscle activity. We have also observed negative deflections of the same type, which we have interpreted as stapedial muscle contractions according to Mendelson's findings (1966). Therefore, whenever we observed a sudden spike-like negative deflection in the "P" channel we always interpreted this pattern to show tensor muscle contraction. When the response was either negative or positive, but the pattern broad and shallow we interpreted this to show stapedial muscle contraction.

The capacity to balance *amplitude* as well as *amplitude and phase* was originally made in order to discover which of the two bridges offers the most easily interpreted responses. It should be mentioned that the two bridges provide responses of different magnitude. The output from the second and third meters is recorded on the first two channels of a four-channel recorder (Mingograf type 34 Elema Schönder) .

Before the reflex measurements are made the middle-ear pressure is always checked by tympanometry. The reason for this is that either abnormal positive or negative pressure may suppress the elicitation of the middle-ear reflexes. The equipment and procedure for tympanometry is described in this issue (Lidén *et al* 1969).

Extratympanic manometry The change in air pressure produced by movements of the tympanic membrane is measured by a pressure transducer and electromanometer (Elema Schönder Type EMT 32 and EM 31) and fed to the third channel of the recorder. The highest sensitivity of the transducer corresponds to a change of ± 0.5 mm water pressure. In order to automatically balance the sensitive pressure transducer for changes in the static pressure in the ear canal an air flow resistor is provided with a time delay of 10 seconds.

Stimulation Pure tones corresponding to five different frequencies (250 500 1000 2000 and 4000 Hz) were recorded on magnetic tape with an intensity range of 40 dB in 2.5 dB discrete steps. The on and off times were one and two seconds, respectively. The rise and decay times were both 25 msec. The signals from the tape recorder were fed through an attenuator system which permitted the preselection of the maximum output for a given

series of tone bursts for each frequency. The system was calibrated in hearing level re: 1964 ISO standard reference. The tones were presented through a TDH 39 telephonic earphone and had a maximum hearing level of 120 dB. However the maximum hearing level employed for most cases was limited to 110 dB.

Air-jet stimulation of the orbital region on the homolateral side of the recorded ear was performed according to Klockhoff & Andersson (1960). Tactile stimulation, according to Klockhoff (1961) and Djupestrand (1964), was performed with a twist of cotton wool on a stick in the homolateral concha and in front of the homolateral tragus, care being exercised to avoid touching the probe.

INTRA AURAL REFLEX RESPONSES

Responses on the amplitude balance meter *A* and on the amplitude and phase balance meter *AP* and on the extratympanic manometer *P* were recorded simultaneously during the presentation of stimuli.

According to Möller (1964) the middle-ear muscles act synergistically as far as impedance is concerned. That could imply an increase in the magnitude of the response in channel *A* when both muscles are contracting simultaneously. However, Figs. 2 b and 2 c show the response to air-jet stimulation for two normal ears in which both muscles are assumed to be functioning, and yet the magnitude of the response is less than in Fig. 2 a, which represents the response of an ear homolateral to supra-stapedial facial palsy with only a functioning tensor muscle. This means that the reflex indicator does not accurately measure the relative impedance change, but instead the change in SPL of the probe tone in the ear canal. Thus, the change of SPL in the ear canal does not appear to be proportional to change of impedance. Depending on the stimulus frequency and the resonance characteristics of the particular middle ear under study channel *A* may show either negative or positive deflections.

The amplitude and phase of the probe tone

are balanced to zero in the AC bridge. Consequently the deflections in this channel ("*AP*") are only positive.

The response *P* indicates the movement of the tympanic membrane. This response is of special interest considering the fact that the tensor muscle presumably pulls the eardrum inward. As this movement occurs, the volume between the probe in the ear canal and the tympanic membrane will suddenly increase and the air pressure will decrease. This situation will appear as a relatively large spike-like negative or downward deflection on the *P* channel of the recorder. An upward or positive deflection on the record indicates an outward movement of the eardrum. This response pattern, unlike the negative downward deflection, is usually a slower shallow broader response and is considered to show stapedial muscle activity. We have also observed negative deflections of the same type, which we have interpreted as stapedial muscle contractions according to Mendelson's findings (1966). Therefore, whenever we observed a sudden spike-like negative deflection in the *P* channel we always interpreted this pattern to show tensor muscle contraction. When the response was either negative or positive, but the pattern broad and shallow we interpreted this to show stapedial muscle contraction.

Subjects

Two groups of subjects were used for this investigation. One group was selected on the basis of pathology which presumably precludes a stapedial muscle reflex. The other group consisted of persons with normal hearing and otologically normal middle ears.

The pathological group contained the following subjects:

- Supra-stapedial facial palsy with otologically-normal middle ears (*N* = 14)
- Unilateral footplate otosclerosis with normal opposite ear (*N* = 13)
- Bilateral footplate otosclerosis with one ear a post-operative stapedectomy (*N* = 12)

The normal group consisted of 78 university students (127 ears). Each had a hearing threshold of 15 dB re ISO or better at test frequencies of 250 to 4000 Hz.

Procedure

All subjects were given an otological examination and a pure tone audiogram prior to the investigation of the middle-ear reflexes. Reflex responses during acoustic stimulation were conducted for all 78 normal subjects (127 ears). Air jet stimulation was performed on 59 of the normal subjects (93 ears) and tactile stimulation of the concha auriculi on 43 subjects (71 ears). Tactile stimulation of the tragus was conducted on 44 normal subjects (70 ears). All of the subjects in the pathological group were tested with acoustic stimulation. Seventeen of the otosclerotic patients were tested by air jet and none by tactile stimulation; all of the patients with facial palsy were given

air jet stimulation and none received tactile stimulation. The reflexes were examined in these subjects by stimulation from tape-recorded pure tones, by an air jet directed towards the homolateral eye and by touching the skin of the homolateral choncha auriculae and on the tragus. In addition, a dual reflex pattern was recorded in seven of the normal subjects during simultaneous acoustic and air jet stimulation. The stapedius muscle was brought into a state of maximum contraction by stimulating the non-recorded ear with a 1000 Hz pure tone, 30 dB above the pre-determined reflex threshold. During this sustained stimulation period of about 12 seconds, three air jet puffs were delivered towards the eye homolateral to the recorded ear. For further comparison, the voluntary contraction of the middle-ear muscles was recorded in two of the normal subjects.

RESULTS

Patients with Supra-stapedial Facial Palsy

None of the 14 patients with facial palsy showed any responses to acoustic stimulation. Air jet stimulation towards the eye homolateral to the recorded ear however gave responses in 10 of the 14 patients. Figs. 2 a and 2 b show the response to air jet stimulation for the recording ear both ipsilateral and contralateral to the supra stapedial palsy in a 71 year-old man. This pattern was similar for all 10 patients in this group who showed a response. For comparison, the responses to air jet stimulation in a subject from the normal hearing group are shown in Fig. 2 c.

Patients with Otosclerosis

None of the 25 patients with otosclerosis showed any activity of the middle-ear muscles upon acoustic stimulation. Seventeen of them were tested with an air jet stimulus directed towards the eye homolateral to the recording ear. Nine patients had stapes fixation in the recording ear and eight had been stapedectomized.

Fig. 2. Response patterns during air jet stimulation towards the homolateral eye. Paper speed 5 mm/sec.
a. Subject E. B. 97 08 26. Unilateral supra-stapedial facial palsy right side. Normal middle ear. No response to acoustic stimulation. Probe in right ear.
b. Responses from left, normal side in same subject as in Fig. 2 a. Normal responses elicited by acoustic stimulation. Probe in left ear.
c. Subject I. S. 44 04 10. Normal subject. Probe in right ear.
d. Subject O. B. 20 05 28. Stapes fixation, right ear. Hearing level 47 dB. No responses on acoustic stimulation. Left ear normal. Probe in right ear.
e. Responses to three air jet from left stapedectomized ear same subject as in Fig. 2 d. No responses were obtained to acoustic stimulation.
f. Subject B. H. 32 11 01. Stapedectomy right ear. Left ear normal. Air jet repeated three times. No responses on acoustic stimulation. Probe in right ear.

Channels A and AP" gave responses to air-jet stimulation in all 17 patients, and channel "P" in 15 patients. All the deflections in channel "P" were sharp negative spikes, thus suggesting tensor muscle contraction. As an example Fig. 2d shows the response to air jet stimulation of the orbital region ipsilateral to the pre-operative otosclerotic ear in a 48-year-old female patient. Fig. 2e shows the response to three air-jet puffs to the eye ipsilateral to the stapedectomized ear in the same patient. Fig. 2f is a further example of the response to three repeated bursts of the air jet to the stapedectomized ear in a 36-year-old male patient.

Normal Subjects

Combined Acoustic and Air Jet Stimulation

Reflex response patterns in seven normal subjects during the combined acoustic and air-jet stimulation were very consistent. The activity of the tensor muscle is superimposed on the reflex elicited by acoustic stimulation and is evident in all three channels. Figs. 3a and 3c represent selected examples of the results of this combined reflex pattern. Figs. 3a and 3b are the response pattern in a 29-year-old normal female. The recording on each channel of each figure readily displays the air-jet response superimposed on the response to acoustic stimulation. Fig. 3c is a similar response pattern in a 28-year-old normal woman.

Voluntary Middle Ear Muscle Reflex

Two normal subjects could voluntarily contract their middle-ear muscles. Their reflex-response patterns were recorded and compared with the responses during air jet as well as combined acoustic and air-jet stimulation. Figs. 4a, 4b and 4c illustrate these responses in a 51-year-old man with normal hearing. Figs. 4a and 4b show what are presumed to be tensor muscle contractions as represented by the sudden, rapid spike pattern displayed. Fig. 4c shows a single tensor muscle contraction resulting from air-jet stimulation superimposed on the response to acoustic stimulation. Unfortunately

none of the subjects with non-functioning stapedial muscles could voluntarily contract the tensor muscle. Thus, we cannot exclude the possibility that responses during voluntary contraction also include a simultaneous stapedial muscle reflex. The general pattern, however is in favour of only a tensor contraction.

Acoustic Stimulation

Altogether data were collected for 127 ears of 78 normal-hearing subjects. The majority of the ears were stimulated with tones of five octave frequencies in the range from 250 Hz to 4000 Hz. In total, 640 frequencies were

used for stimulation in the 78 subjects. In 80 % of the frequencies, a maximum HL of 110 dB was used, and in 20 % 120 dB HL was used.

All of the 127 ears gave clear responses on

channels "A" and "AP". On channel P, on the other hand, responses were recorded for only 44 % of all frequencies tested. A positive deflection, as shown for example in Fig. 5a, was noted in 26 % of all tested frequencies. Translated to percentages of subjects, the results show that 51 % of the 78 subjects had responses with positive deflection at some of the frequencies tested. It should be remembered that a positive deflection in channel "P" is interpreted as a stapedial muscle response (S+).

In 14 % of all tested frequencies, or in 30 % of the subjects, a shallow broad negative deflection was found for some of the frequencies (Fig. 5b). Since these responses do not show the sharp spike like negative pattern, they were interpreted as the result of stapedial muscle contraction (S-).

A very large negative deflection increasing with intensity of the acoustic stimulation was used as a criterion for a tensor muscle response (T). In 10 of the 78 subjects, or nearly 13 % such a response was observed (Figs. 6a, 6b and 6c). However, calculated on the basis of all tested frequencies there was evidence of

Fig. 6. Response patterns in normal subjects during acoustic stimulation. The sharp spike like negative deflections in channel P are interpreted as tensor reflexes.

tensor activity in only 4 % of the measurements. An isolated negative or spontaneous response which could not be repeated was disregarded.

Air Jet and Tactile Stimulation

Recordings during air jet stimulation directed towards the homologous ear were obtained on 13 normal ears. The concha auricularis and tragus of 71 and 70 ears, respectively were coated with a twist of cotton wool attached to an applicator. The results are shown in Table 1. Stimulation of the concha seems, according to this investigation, to give better responses than on the tragus.

COMMENTS

The reflex pattern in channel "P" indicating induced movement of the tympanic membrane, was used primarily to identify the activity of the tensor muscle. Sharp, spike-like negative deflections, increasing with the intensity of the acoustic stimulus, were interpreted as tensor contractions. A change in the reflex pattern of channels A and AP" simultaneously with the appearance of these spike-like deflections lend additional support to this assumption. The identification was also based on investigations of reflex patterns in the subjects in whom the tensor was the only

functioning muscle in the middle ear. Likewise, the reflex patterns during the combined acoustic and air jet stimulation as well as during the voluntary contraction of the middle ear muscles, contribute to a clearer recognition of the tensor response. The tensor reflex, identified by a negative deflection which increases in magnitude with an increase in the intensity of acoustic stimulation, was found in only 13 % of our normal-hearing subjects. About half of these tensor responses appeared first at levels above 110 dB HL. However nearly as many appeared starting at about 100 dB HL.

The tensor reflex during air-jet stimulation has been considered to be part of a startle reaction. Strong squinting of the eyes or contraction of the muscles of the face may elicit the tensor reflex. For this reason, the subjects were observed closely during the period of acoustic stimulation. None of the subjects with apparent tensor responses gave evidence of intolerance or reacted with facial muscle contractions. Thus, we feel it is justified to consider the recorded response in this minority group of normal subjects as an acoustic tensor reflex. In the group with pathological middle ears in which the tensor muscle was the only functioning muscle the tensor reflex could not be elicited by acoustic stimulation for any subject. Tables 2 and 3 summarize the results of acoustic and air-jet stimulation.

Table 2 Impedance and extratympanic manometry responses in per cent during acoustic and air jet stimulation for all subjects

	Pure tones Channels				Air Jet Channels			
	N	A	AP	P	N	A	AP	P
Facial palsy	14	0	0	0	14	70	70	70
Stapes fixation	13	0	0	0	9	100	100	90
Stapedectomy	1	0	0	0	8	100	100	90
Normal subjects	78	100	100	8	49	97	94	81
Number of frequencies	640	100	100	44				

CONCLUSIONS

Simultaneous recording of changes in relative impedance and air pressure give a more complete picture of the behaviour of the middle-ear muscle reflexes. By this method it is easier to identify the response of the tensor muscle.

Extratympanic manometry may provide interesting supplementary information. However in our opinion this technique is not necessary for diagnostic purposes. In our judgement, response patterns on the reflex indicator and on the manometer during acoustic stimulation are primarily due to the stapedial muscle reflex, i.e. these responses can be observed on a reflex indicator without the aid of a manometer.

In a small fraction of the group of normal subjects (13 %) the recording patterns suggest that both muscles contract during acoustic stimulation. The stapedial muscle appears to have a reflex threshold at a lower sound pressure level than the tensor muscle.

DISCUSSION

K. Terkildsen. I do not understand why contraction of the tensor muscle can cause a reduction in the tympanic membrane impedance. These "negative" reflexes come with a very short latency and the mechanism of this type of response must still be kept under discussion.

Neergaard. It should be noted in connection with the evaluation of pressure changes in the ear canal that an inward displacement of a curved membrane may well give rise to a volume displacement in the opposite direction. So a recording of volume displacements or pressures is not sufficient for the assessment of the movements of the central part of the membrane.

G. Lidén (Reply to Terkildsen). The middle ear muscles act synergistically as far as impedance is concerned. The reflex indicator, however, does not accurately measure the relative impedance change, but instead the change in SPL of the probe tone in the ear canal. Thus, a simultaneous contraction of both middle-ear muscles behaves antagonistically as far as measurement of a change in SPL is concerned, reducing the magnitude of the response.

(Reply to Neergaard). You are right. As I mentioned, Mendelson (1966) pointed out the same thing.

TYMPANOMETRY

A METHOD FOR ANALYSIS OF MIDDLE EAR FUNCTION

G Lidén, J L. Peterson and G Björkman

*From the Department of Audiology Sahlgren's Hospital Göteborg and
Louisiana State University School of Medicine New Orleans, Louisiana U S A*

Tympanometry is a method for evaluation of the mobility of the ear drum and the functional condition of the middle ear. This is performed by measuring the ability of the tympanic membrane to reflect a probe tone in response to gradually changing air pressure in the ear canal. Four tympanometric characteristics were measured in a series of 100 normal ears. These results were compared with those obtained in patients with different types of conductive pathology. The observed patterns in these patients with different audiological diagnoses were confirmed by surgery and by comparison with a series of fresh human temporal bones in which discrete lesions were created.

Tympanometry is a technique used to assess the mobility and the condition of the tympanic membrane and the middle ear during variation of the air pressure in the ear canal (Andersson *et al* 1956, Terkildsen & Thomsen 1959, Klockhoff 1961, Lidén & Nordlund, 1962, Hallén *et al* 1964, Lidén, 1969 a, 1969 b).

Tympanometry has been used as a routine clinical test in the Audiology Department, Sahlgren's Hospital, Göteborg since 1961. The purpose of this study was to evaluate systematically particular tympanometric characteristics for stability of response in normal ears, compare these results with those obtained for various pathological conditions and assess such differences as an aid to diagnosis.

Subjects

A series of 100 otologically normal ears from subjects with a mean age of 27 years was studied to provide baseline data. The conductive group composed of 28 subjects with a mean age of 41 years, had various pathological mid-

dle-ear lesions, i.e. otosclerosis, secretory otitis media, chronic adhesive otitis media and disruption of the ossicular chain. A sensorineural group with a mean age of 47 years consisted of 20 subjects and was included in the investigation for comparison purposes.

Equipment

The basic instrument for tympanometry is the intra aural reflex indicator with probe unit described by Lidén *et al* (1969 a, 1969 b). A simplified block diagram is shown in Fig. 1. An 800 Hz probe tone is generated by the oscillator circuit of the reflex indicator and routed to a hearing aid type receiver mounted in the housing at the end of the probe unit. This signal is directed through one channel of the probe which is sealed by a foam-plastic cuff in the external auditory canal. The pick up microphone in the probe unit monitors the sound pressure level in the ear canal between the tympanic membrane and the cuff of the probe. The SPL of the probe tone is displayed on a meter of the reflex indicator. The air pump unit creates a continually changing air pressure in the ear canal from -200 mm water to +200 mm water over 45 seconds. This change in air pressure is monitored by a pressure transducer and electromanometer (Elema-Schönander type EMT 34 and EM 31). The tympanogram i.e. the reflection of the probe tone indicates the change of impedance of the tympanic membrane due to the induced air pressure load. The probe tone is adjusted to 70

Fig. 1 Simplified block diagram of the equipment.

dB SPL at the starting point of -200 mm water. The tympanogram with its corresponding air-pressure load is simultaneously displayed on a Mingograf recorder.

Procedure

All subjects had an otological examination and hearing tested by pure-tone audiometry. Speech audiometry was also performed for all subjects in the conductive and sensorineural groups. Tympanometric curves were then obtained.

Three subjects in the normal group were selected for a reliability study of the tympanometric curve. Twenty tympanograms were obtained for the experimental ear of each subject over a 10-hour period.

The four measured tympanometric characteristics are illustrated in Fig. 2 for a 25-year old female with normal hearing and a normal

tympanic membrane and middle ear. The V-shaped curve shows the tympanogram. The diagonal line is a recording of the air pressure change from -200 mm to $+200$ mm water. The first characteristic is the "V" or notch, which is measured in dB.

The second characteristic is the position of the notch relative to zero air pressure. The third characteristic is the width of the notch. It is found by determining half the maximum depth of the notch in dB and projecting this point to the intersection with the negative and positive halves of the tympanogram. These points are then projected to the diagonal pressure line where the width is measured in mm water. The fourth characteristic measured in defining the tympanogram is the difference in SPL between the two end points of the tympanogram (upper right, Fig. 2).

Fig. 2 Tympanometric characteristics for a 25-year old woman with normal hearing, normal tympanic membrane and middle ear. The V-shaped curve shows the tympanogram. The diagonal line is recording of the air pressure change from -200 mm to $+200$ mm water.

Table 1 Means and standard deviations of tympanometric characteristics for subjects in the normal group otosclerotic ears in the conductive group and the sensorineural group

Otoscler	\bar{X}	5.4	-38.8	+92.6	+ 3.3	1.5
N = 29	SD	± 2.0	± 30.1	± 50.0	± 27.3	± 0.6
Sen. neur	\bar{X}	4.8	-45.4	+96.5	+ 2.8	1.3
N = 27	SD	± 1.7	± 25.1	± 58.4	± 26.1	± 0.1

RESULTS

Means and standard deviations for all normal ears, those with otosclerosis from the conductive group and all subjects in the sensorineural group are shown in Table 1. The four measured characteristics of notch depth, notch width, deviation from atmospheric pressure for the notch and the difference in SPL between maximum and minimum air pressures are approximately the same in all three groups. This observation was supported by a statistical analysis, which showed no significant difference among the groups. Fig. 3 illustrates the mean curves for the three groups. This comparison shows a highly similar pattern to the curves for each group.

The results for three normal subjects selected for the reliability study did not show any statistical difference either when within-subject comparison were made (Table 2). These results indicate good stability for tympanometric con-

figuration when a subject serves as his own control. The standard deviations for the normal group (Table 1) also show little spread around the obtained means, indicating good between-subject stability as well. Fig. 4 illustrates the first, fifth, tenth, fifteenth, and twentieth tympanograms for subject 1 obtained over the 10-hour test period. Similar internal relationships were observed for subjects 2 and 3.

Tympanograms obtained for those subjects in the conductive group with sequelae of various types of otitis media and disruptions of the ossicular chain were different in many respects. Fig. 5 A shows the tympanogram of the right ear for a 63-year-old man with a large thin scar in the posterior half of the tympanic membrane after recurrent otitis media. The hearing tests gave no support to diagnosis of disruption of the ossicular chain. The two sharp distinct peaks ("W" pattern) near zero air pressure represent the points of greatest tympanic membrane mobility. The tympanogram for the left

ear (not shown) resulted in a flat straight line caused by a perforation.

Fig. 5 H shows the tympanogram for the left ear of a 9-year-old boy with recurrent colds. Otoloscopic examination revealed a retracted membrane. The tympanogram shows a dramatic shift of the notch to approximately -200 mm water resulting from an abnormal negative air pressure in his middle ear.

Fig. 5 C shows the tympanogram for a 10-year-old boy with a history of conductive hearing loss and serious otitis media, bilaterally. Otoloscopic examination showed a retracted left tympanic membrane with effusion in the middle ear. The right tympanic membrane was normal, but effusion was also present in this middle ear. The tympanograms for both ears are similar showing an extremely flat, saucer-shaped curve. Only the curve for the right ear is illustrated.

Disruption of the ossicular chain will also produce an abnormal tympanogram. Fig. 5 D

shows such a curve for a 66-year-old man with a history of chronic otitis media. Otoloscopically the right ear showed a large atrophic scar in the posterior superior quadrant with abnormally high mobility when evaluated with the Siegle loupe and pressure bulb. Audiologically erosion of the long process of the incus was suspected and was later confirmed at operation. The tympanogram showed a highly irregular pattern across the entire air-pressure range. The tympanic membrane scarring plus erosion of the long process of the incus are undoubtedly the causal factors for the unusual shape of this curve.

The tympanogram for the right ear of a 38-year-old woman who had been operated on for otosclerosis is illustrated in Fig. 5 E. Stapedioplasty had been performed on this ear in 1966. Otoloscopy in the present examination, revealed a small atrophic scar in the upper posterior quadrant. The hearing had returned to near the pre-operative level. Based upon the

Fig. 4. Test-retest comparison of five tympanograms for subject 1 obtained over a 10-hour period.

Fig. 5 Abnormal tympanometric curves.

A. Right ear tympanogram for a 63-year-old man with a large thin scar in the posterior half of the tympanic membrane and a history of recurrent otitis media.

B. Left ear tympanogram for a 9-year-old boy with recurrent colds and a severely retracted tympanic membrane indicating abnormal negative pressure in his middle ear.

C. Right ear tympanogram for a 10-year-old boy with a history of conductive hearing loss and bilateral serous otitis media with effusion in the middle ear.

D. Right ear tympanogram for a 66-year-old man with a history of chronic otitis media and a large atrophic scar in the posterior superior quadrant of the tympanic membrane and abnormally high mobility of the ear drum as evaluated with the Single tone. Erosion of the long process of the malleus was suspected and later confirmed at operation.

E. Right ear tympanogram for a 38-year-old otosclerotic woman on whom stapediolysis had been performed in 1966. At the present examination a small atrophic scar was found in the upper posterior quadrant. Fracture of both crura was also suspected at this time and later confirmed during stapedectomy surgery.

F. Left ear tympanogram for a 22-year-old man on whom stapedectomy had been performed for otosclerosis. Otoscopy revealed a normal-appearing, but by permobile tympanic membrane.

tympanogram, fracture of both crura was suspected. This was confirmed during subsequent surgery. The tympanogram shows a large broad undulating peak to the negative side of atmospheric pressure.

Fig. 5 F shows the post-operative tympanogram for the left ear of a 22-year-old man with otosclerosis upon whom a stapedectomy procedure had been performed. The pre-operative curve (not shown) was quite normal. The post-operative curve obtained 3 months after surgery shows a peak similar to that in Fig. 5 E deflected to the negative side of zero air pressure. Postoperative otoscopy showed a supermobile tympanic membrane. Many stapedectomized ears have less than normal mobility. The tympanograms in these postoperative otosclerotic ears have normal shape with the prostheses in place. More often, however, an

abnormal tympanogram is found in a post-operative otosclerotic ear. The exact shape of it will vary in detail, but the basic pattern will be similar to that shown in Fig. 5 F.

DISCUSSION

Tympanometry provides a method of evaluating tympanic membrane mobility, the air cushion of the middle ear and the integrity of the ossicular chain and associated structures. It provides clinically useful information which can be obtained by no other currently available test.

A normal tympanic membrane and middle ear will show a smooth, notched curve over an air-pressure range from -200 to +200 mm water with the notch occurring near atmospheric pressure. Measurement of the four tym

panometric characteristics will closely approximate the data presented in Table 1 for the 100 normal ears when 800 cps is used as the probe frequency.

In otosclerosis where no pathology other than stapes fixation is present the normal configuration of the tympanogram is not distorted. The same is true for all patients with sensorineural lesions.

Several distinctive tympanometric curves can be identified as related to specific pathological conditions:

- 1 Flat, straight-line pattern. This curve will be found in ears which show a tympanic membrane perforation, a serous otitis media or chronic adhesive otitis media. The tympanic membrane is unresponsive to the applied air pressure either because of the perforation or because the tympanic cavity is filled with fluid, exudate or adhesions.
- 2 Rapid, oscillatory patterns near pressure balance point ("W" pattern). This shape will be seen frequently in patients with tympanic membrane scarring.
- 3 Large, broad undulating peaks. Curves of this kind can be observed in patients with disruptions of the ossicular chain. This pattern has also been seen in otosclerotic patients who have undergone stapedectomy.
- 4 Tympanometric pressure-balance point deviated to the negative side of atmospheric pressure, indicating negative middle-ear pressure. This pattern is seen in impaired Eustachian-tube function. The extent to which the notch is shifted can show a relationship to elevated reflex thresholds or air-bone gap seen in pure-tone audiometry (Peterson et al.).

A slight deviation of the notch to positive pressure does not seem to be a pathological sign, but evidence of good tubal function. In fact, the normal group showed a deviation corresponding to +10 mm water (Table 1). The otosclerotic and sensorineural groups both showed a positive pressure in the middle ear corresponding to +3 mm water. The standard de-

viation in the normal group was ± 15 mm and about ± 27 mm in the pathological groups. Furthermore, reversing the ear-canal air-pressure change, to run the test from plus to minus 200 mm water does not alter the results. This minor deviation of the notch from atmospheric pressure is presumably due to a hysteresis effect of the impedance of the tympanic membrane resulting from the applied pressures. Thus, a minor residual positive pressure shown by tympanometry is presumed to indicate normal tympanic membrane behaviour and tubal function.

The above four patterns represent the basic shapes that have been observed. Minor variations will be seen in the patients, but significant departures from these patterns would not be expected. It is our experience that frequently a combination of abnormal conditions will be present resulting in a tympanogram not typical of any of the above patterns.

In order to identify the tympanometric effect of pure lesions, a series of fresh human temporal bones was studied by Peterson & Liden (1969). Discrete experimental lesions were created in the middle ears of the bones and tympanometric shapes observed. For example, fracturing the crura or separating the joint between the malleus and incus or between the incus and stapes produced tympanograms similar to those shown in Figs. 5 D-F. Filling the middle ear with water resulted in a tympanogram similar to that seen in Fig. 5 C. A negative or positive pressure applied to the middle ear of these bones shifted the notch to the left or to the right to a point at which the air pressures on both sides of the ear drum corresponded. These results have permitted interpretation of tympanograms in living ears with greater assurance.

Tympanometry is of significant clinical value. A pathological shape to the tympanogram when it is not expected alerts the surgeon and will permit him to judge the potential success of the planned operation. For this reason, as well as others illustrated above, tympanometry has become a routine diagnostic test for all

cases with middle-ear lesions seen in our department.

REVERSE FREQUENCY SWEEP BÉKÉSY AUDIOMETRY

J. Kärjä and A. Palva

From the Department of Otolaryngology University of Oulu, Finland

A Grason-Stadler E800 Békésy audiometer was used for threshold measurements with sweep-frequency technique starting from the low tones (forward) and then from the high frequencies (reverse). The tracings were superimposed for both interrupted and continuous tones in normal-hearing subjects and in cochlear deafness. In some cases, most frequently in retrocochlear lesions, the reverse tracing was poorer than the forward curve for continuous tones in the middle and/or high-frequency regions. This behaviour was associated with pronounced threshold tone decay and, almost without any exceptions, with negative or incomplete recruitment.

In Békésy audiometry the conventional threshold measurements are carried out with interrupted and/or continuous stimuli starting from low tones. On the basis of these tracings, Jerger (1960) and Jerger *et al.* (1962) described four separate types: in normal hearing continuous and interrupted tone tracings overlap (type I) in cochlear deafness the continuous tone tracings may be poorer at the high frequencies (type II) the separation may be very pronounced in the middle and high range (type III) or it occurs at all frequencies (type IV). Type III is often associated with retrocochlear deafness. Corso & Wilson (1951) utilized a reverse frequency sweep in testing 10 normally hearing subjects. With continuous and interrupted stimuli the thresholds for high frequencies were found to be better with the forward sweep than with the reverse sweep; the opposite was the case in the low frequencies. In Epstein's (1960) 15 subjects with sensorineural deafness the thresholds tested in the range 200-4000 cps were poorer at 3000 cps

with the forward sweeping than when the reverse order was used.

The measurements of Rose (1962) in 47 patients with perceptive deafness were made with pulsed and continuous tones between 100 and 10 000 cps using the attenuation rate of 2.5 dB/sec. In mild hearing loss (20 dB or less) the thresholds were generally not affected. His case histories, including both cochlear and retrocochlear lesions, suggested that the reverse frequency sweep gives poorer thresholds in high- or middle-frequency regions. In some cases, when the conventional forward method did not reveal an interrupted-continuous tone gap such a gap was demonstrated with the reverse frequency sweeps.

TESTING TECHNIQUE AND MATERIAL

The apparatus used was a Grason-Stadler Model E 800 Békésy audiometer operating at SPL with a 0.0002 dyn/cm² zero-level at all frequencies. The test subject was instructed to press the switch immediately a tone was heard and to release it as soon as the tone disappeared. With an attenuation rate of 4.2 dB/sec., the sweep over the frequency region 125-8000 cps took 3½ min. The testing was started from the low tones, the reverse frequency sweep following after a pause of a few seconds. Tests were made with interrupted and continuous tones; the former consisted of 200 msec pulses with a rise and fall time of 25 msec, presented at intervals of similar length.

cases with middle-ear lesions seen in our department.

Fig. 1 Békésy tracings registered by two-octave technique for the affected frequencies 2000–8000 cps in a patient with hyperension and angiodystrophic cerebral disorder. The overlapping upper pair of curves are the forward and reverse tracings with interrupted test tone. The continuous tone tracings lie definitely apart: the forward curve (middle) is clearly better than the reverse (bottom). Threshold tone decay test shows total disappearance of test tone at 4000 cps in 90 sec. there is incomplete recruitment at 4000 cps.

Although the poor reverse threshold was accompanied with pronounced threshold tone decay the latter could appear in association with a normal reverse sweep. Thirty-one ears with threshold tone decay of 30 dB or more (in two cases over 60 dB) showed overlapping tracings, in 20 cases recruitment was complete, in five ears absent, and in six cases incomplete.

Compared with Jerger's classification, abnormally poor reverse tracings occurred among all four types, two cases even representing type I. A similar distribution is seen in the cases reported by Rose. It seems that abnormal adaptation is the most likely explanation for the

separation of the tracings, even if the exact mechanism is obscure. It is known that post-stimulatory threshold shift after low-intensity exposure is nearly symmetrical around the stimulus frequency. It has, however, a tendency to spread towards the high frequencies. After high intensity stimulation, the maximum threshold shift occurs half an octave above the stimulating frequency. Thus, the forward continuous-tone sweep might be expected to give poorer threshold values than the reverse test, indeed, Epstein (1960) and Harbert & Young (1962) reported such results. In agreement with Rose's results (1966) we were unable to con-

Table 1 Results in patients with sensorineural hearing loss

Diagnosis	Patients	Ears	Abnormal tracings
Ménière's disease	38	38	1
Acoustic trauma	16	23	1
Noise injury	30	47	
Streptomycin damage	6	8	
Postinfectious deafness	8	8	
Vestibular neuronitis	4	4	
Vascular accident	9	9	1
Angiosclerotic degeneration	24	37	2
Head injuries	25	31	6
Presbycusis	16	24	
Hereditary or congenital deafness	18	26	1
Infratentorial tumour	4	2	2
Supratentorial tumour	1	1	
Diffuse central lesion	10	12	1
Functional hearing loss	2	2	1
Undetermined sensorineural deafness	12	14	1
Total	221	284	17

If there was any abnormality between tracings, control measurements were made in the affected area with the two-octave frequency sweep technique. Preliminary measurements were made on both ears of three experienced observers and on one ear of 10 normally hearing inexperienced listeners (Palva *et al.* 1969). The series consisted of 221 patients with sensorineural hearing loss: the number of tested ears totalled 284. In addition to air and bone conduction conventional threshold measurements, speech audiometry, recruitment testing by Fowler's or Reger's method and the threshold tone decay test were employed.

RESULTS

The results in the patients with sensorineural hearing loss are presented in Table 1. In 17 of the 221 patients there was a separation of the continuous tone tracings exceeding 10 dB and it was always the reverse frequency sweep that gave poorer threshold values than the forward testing order. The separation appeared most often at the high and middle frequencies, occasionally also at low tones. It was always

accompanied with a pronounced threshold tone decay (30–60 dB in 3 minutes, the test tone often disappearing totally) and with incomplete or negative recruitment (exceptions were one patient with Ménière's disease and another with acoustic trauma). The amount of separation was in most cases 30–50 dB. The forward and reverse tracings with interrupted test tones were superimposed in each of the cases studied.

The patients with separated reverse tracings included two with severe angiosclerotic disease. Two patients had an infratentorial brain-base tumour and one patient a diffuse central lesion resulting from meningo-encephalitis. In a subgroup of 25 patients with head injuries, abnormal tracings were observed in six. They had all sustained severe injury with cerebral contusion. A vertebral artery occlusion was found in one case of vascular accident. A separation between the forward and reverse sweeps was observed in only two cases of pure cochlear lesion. In one, the patient suffered from Ménière's disease and medication had proved ineffective but attacks were later relieved after decompression of the endolymphatic sac; the other patient had an old acoustic trauma with troublesome tinnitus.

Fig. 1 shows a typical result obtained by testing the affected frequencies with the two-octave technique. The patient suffered from hypertension with angiosclerotic degeneration. She was under examination because of vestibular symptoms.

DISCUSSION

In this series of perceptively deaf ears the abnormal separation of the forward and reverse Békésy tracings was always accompanied with pronounced threshold tone decay and generally with negative or incomplete loudness recruitment. Accordingly the abnormally poor reverse tracings were as a rule associated with retrocochlear lesions (Table 1) and only twice with a pure cochlear lesion with complete recruitment.

AUDIO-VISUAL SPEECH PERCEPTION

A PRELIMINARY REPORT

H. W. Ewertsen, H. Birk Nielsen and S. Scott Nielsen

From the Stat. Hearing Rehabilitation Centre Bispebjerg Hospital, Copenhagen, Denmark

By means of a video-recorder connected to a speech audiometer and television set it is possible to vary independently the two parameters, the picture and the sound level. The communication score of 100 persons is formed in relation either to the visual perception alone or to the auditive perception and, finally to combination of both. In the group of patients with medium lipreading ability there seems to be fairly good correlation between this ability and the reduction of their hearing loss measured in decibels. A small group seems to have special capacity of combining vision and hearing.

It is a well-known fact that vision can, to a variable extent, substitute failing audition. The easiest words to lipread are numbers, because the possibilities of guessing are few but the ability of various people to lipread other words varies in correctness from 0 to 100 %.

During the last few years we have tried objectively to evaluate the lipreading ability of our patients by exposing them to a silent colour film of about three minutes duration representing the familiar situation of two people having coffee together and saying nine sentences in all.

Two years ago we bought a video-recorder (Philips). This is a kind of tape-recorder by means of which a picture and the connecting speech can be reproduced on a TV set, on which the intensity of the speech can be adjusted in decibel steps through the audiometer. By means of this equipment it is possible independently to vary the two parameters—the visual and the auditive perception.

We had some discussion regarding the selection of speech material and how to quantify the performance of the patient. Should he repeat every single word in each sentence, or

was it satisfactory if he perceived the meaning of the sentence? After some introductory experiments, we began to use short sentences giving instructions to the patients, such as: Rub your nose, "Cross your arms", Lift your foot" etc. It was then recorded whether or not the patient actually did as he was told. This procedure was approved by our test psychologist Jan Ratteff.

The patients are tested in three situations:

1. *Hearing Alone*

We start with five sentences presented 10 dB below the patient's speech-reception threshold, and then five sentences at the threshold, five sentences 10 dB above threshold, five sentences 20 dB above threshold, five sentences 30 dB above threshold.

2. *Vision Alone*

The same 25 sentences, but in a different sequence.

Fig. 1 Audiogram of a patient with high-tone loss. The speech-reception threshold is 40 dB in either ear. At each of the indicated hearing levels five sentences (orders) are given, and the number of errors is stated.

firm these findings in any case. Control runs were also carried out: the sweep was started at the high frequencies and the forward frequency sweep followed next. However the results in abnormal cases were the same as in the conventional order of frequency testing: neither did the results differ from one another in overlapping cases.

The forward and reverse frequency sweeps seem to give more information than conventional Békésy audiometry. Our results indicate that abnormal results are obtained in a certain number of those cases of hearing impairment that show great fatigability or much adaptation. It remains to be seen whether with added

experience, a definite diagnostic value can be assigned to this interesting phenomenon.

CLICK-EVOKED RESPONSES IN THE MEDIAL GENICULATE BODY IN AWAKE CATS

B. Etholm, L. Ohen and K. Skrede

From the Institut of Neurophysiology University of Oslo, Norway

A method for recording from the medial geniculate body in awake cats is reported. The pattern of the response was similar to that seen in anesthetized cats. By using double clicks, there was depression of excitability following an excitatory response which lasted only 20–30 msec. Giving the animal barbitalum amacethale (30 mg/kg), the inhibitory period was greatly prolonged.

Fig. 2. The abscissa indicates how many sentences the patient is able to perceive through lipreading with out sound. The ordinate shows by how many decibels the speech-reception threshold is reduced when the patient combines lipreading and hearing.

quence are presented on the TV screen without sound.

3 Hearing and Vision Combined

The 25 sentences are said by the speaker on the TV screen, and the sound is gradually increased in 10-dB steps from 20 dB below threshold to 20 dB above threshold.

The procedure of testing a patient is illustrated in Fig. 1

CLINICAL MATERIAL

This preliminary report is concerned with the results in our first 100 patients representing all kinds of hearing disorders and with a speech-reception threshold varying from 30 to 70 dB the average being 50 dB (H. L.)

The relationship between vision and hearing was plotted in a diagram (see Fig. 2). Eighteen patients were so clever at lipreading that they

were excluded from the diagram, because this group was not suitable in an investigation of the relationship between vision and hearing.

Fourteen patients did not understand a single sentence through lipreading alone, but nevertheless it is seen on the ordinate that the combination of hearing and vision improved their speech perception.

This is in good agreement with the fact that normally hearing persons also feel that they understand better when they are able to observe the face of the speaker.

Fifty three patients are grouped in the lower part of the diagram. We found that the better the patients were at lipreading, the more could the intensity of the speech be reduced, still giving the patients 100 % perception.

The 15 patients represented by circles in the upper part of the diagram are a statistical mystery to us. We cannot explain why this group of moderately good lipreaders were able to communicate with the introduction of sound which was so faint that they merely perceived the rhythm of the message. This suggests a certain capacity of combining the two senses of hearing and vision.

The largest group consisting of 53 patients showed a fairly good correlation between lipreading ability and reduction of speech intensity and perhaps we shall be able to express lipreading ability in physical terms of dB in the future, and with this aim in view we continue our work with the video-recorder.

DISCUSSION

N Riskær Do you have any experience as regards the visual test with normal-hearing persons?

Do you know how much training in lipreading can improve the result in patients with impaired hearing?

H V Ewertsen (Reply to Riskær) Twenty five normally hearing subjects were examined in the preliminary research and a few of them were fantastically proficient in lipreading.

CLICK EVOKED RESPONSES IN THE MEDIAL GENICULATE BODY
IN AWAKE CATS

From the Institute of Neurophysiology University of Oslo Norway

A method for recording from the medial geniculate body in awake cats is reported. The pattern of the response was similar to that seen in anesthetized cats. By using double clicks, there was depression

of excitability following an excitatory response which lasted only 20–30 msec. Giving the animal barbitalurate anaesthesia (30 mg/kg), the inhibitory period was greatly prolonged.

EARLY DIAGNOSIS OF EIGHTH NERVE TUMOURS BY ACOUSTIC REFLEX TESTS

H. Anderson, B. Barr and E. Wedenberg

From the Department of Audiology Karolinska Hospital, Stockholm Sweden

Acoustic reflex tests were performed in 12 cases of tumour of the acoustic nerve and five tumours of the posterior fossa so located as to affect the nerve. The acoustic reflex threshold was pathologically elevated in all 17 cases, and in seven cases so much that the reflex could not be acoustically elicited. In the 10 cases in which the reflex threshold could be attained, the response showed an abnormally rapid fatigue on prolonged stimulation a phenomenon here termed "reflex decay". The observations indicate that the reflex-decay phenomenon is the earliest audiological sign of an incipient lesion to the acoustic nerve and hence it is of great value in the early diagnosis of acoustic tumours.

In clinical diagnosis, retrocochlear lesions in the form of acoustic tumours occupy a unique position. Interest in them is by no means related to their incidence on the contrary their proportion in a normal clinical audiological series is less than should be assumed from the abundant literature on the subject. At the Neurosurgical Clinic, Karolinska Sjukhuset, about 20 acoustic tumours are operated on each year. More than half of the patients have such severe hearing impairment when referred for examination that a differential-diagnostic hearing test of any kind is out of the question. In relation to the total number of patients examined annually at the Department of Audiology of this hospital the chance of encountering a case with such audiometrically identifiable damage has a probability of less than 1/1000. This low incidence in itself implies a risk that these cases will be overlooked. More recent investigations have shown that these tumours are not associated with such uniform audiometric patterns as was earlier be-

lieved particularly at the early stages (Johnson, 1966; Shapiro & Naunton, 1967).

Good agreement is normally regarded to be present between the subjective, "true" test of recruitment (e.g. Fowler's test) and the objective recruitment determination provided by the acoustic intra-aural reflex (Kristensen & Jepsen, 1952; Metz, 1952; Thomsen, 1955; Anderson & Barr, 1966). Since the lack of recruitment is one of the salient features of retrocochlear hearing impairment (Dix *et al.* 1948; Goodman, 1957; Johnson & Sheehy 1966), it was considered of interest systematically to study the potentialities of this test for establishing an early diagnosis of disorders in the acoustic nerve.

MATERIAL

The series studied consisted of 17 patients with verified retrocochlear involvement with a hearing loss not exceeding 60 dB (mean 500, 1000 and 2000 cps). Six of the patients still had a hearing threshold within the normal variation, when due regard was paid to age, sex and occupation. In 12 cases the diagnosis was a tumour of the acoustic nerve: five were classified as tumour of the posterior fossa with such localization that they involved the acoustic nerve. Of the cases, 15 were verified surgically and the remaining two were identified radiologically.

METHODS

The equipment used for reflex measurement

Fig. 1. The reflex response on prolonged stimulation recorded in a normal ear

has previously been described by Klockhoff (1961) and Anderson (1969). Reference should be made to these papers for a more detailed account.

The acoustic reflex measurement can be used to solve a number of problems in hearing diagnosis of interest in the present context are the responses that can be recorded when the lower of the two intra-tural muscles, the stapedius muscle, is induced to contract. This muscle is the effecting organ in a reflex arc whose afferent pathway consists of the sensory cells of the cochlea and the acoustic nerve. In sound stimulation of moderate intensity a reflex contraction is elicited in the stapedius muscle, and the degree of contraction increases with the intensity of the stimulus within a fairly large dynamic range. The reflex response can

thus be used as a measure of the afferent inflow through the sensorineural system of the ear at supra-threshold levels.

By ascertaining the lowest intensity at which recordable responses are obtained at different test frequencies—just as in the usual hearing threshold audiogram—a reflex-threshold curve is recorded. If then the stimulus tone is presented at definite levels above this reflex threshold, a relative measure of the strength of the muscle contraction in the form of response amplitude is obtained. These functions have been examined in previous studies, in which certain pathological criteria were also formulated.

Another interesting feature of the reflex response is its persistence on prolonged acoustic stimulation. Fig. 1 shows a representative recording in a normal ear: the test was performed at 500 1000 2000 and 4000 cps at a level of 10 dB above the reflex threshold and with a stimulus duration of 10 seconds. At the lower test frequencies no fatigue at all is observed in this period, at 2000 cps a small but significant reduction in the response amplitude is noted, and at 4000 cps this reduction is marked. This phenomenon has been termed "reflex decay" it is quantified as the time (in seconds) for the

Decay of acoustic reflex magnitude (amplitude) of prolonged stimulation 50 normal ears.

Stimulus duration 10 seconds 10 dB above individual reflex threshold level

Fig. 2. Half-life points of responses indicated by continuous arrows: dash-dotted arrow is the limit of recording accuracy. Shaded area: Semi-interquartile range.

Table 1 Result of differential-diagnostic hearing tests (acoustic tumours 12 posterior fossa tumours 5)

	Speech discr.	Fowler's test	Thres- hold decay
Tested	17	14	16
Positive	8	9	8
Proportion of positive tests, %	47	64	50

response amplitude to be reduced by 50 per cent.

Fig. 2 shows the mean persistence of the response for 50 ears of young subjects with normal hearing. No reduction in response amplitude is observed for the lower test frequencies, whereas the median half-lives of the responses for 2000 and 4000 cps are 14 and 7 seconds respectively (Anderson *et al.* 1969).

RESULTS

The results of the traditional hearing tests used in differential diagnosis namely speech discrimination, Fowler's test and the hearing threshold decay test, are found in Table 1. These tests were positive in only about 50 per cent of the applications, a degree of unreliability that is a well-documented feature.

As regards the results of the reflex measurements the reflex threshold was pathologically elevated in all 17 cases in seven cases so much that the reflex could not be elicited even at maximum available sound stimulus (120 dB hearing level).

In the 10 cases in which the reflex threshold could be attained however there was yet another interesting feature in the reflex response viz an abnormally rapid fatigue on prolonged stimulation. As has previously been shown there is normally no measurable reflex decay for the frequencies 500 and 1000 cps. For the tumour group there was a marked reflex decay the response amplitude for these frequencies being halved in about 3 seconds

in none of the subjects at any of the test frequencies was the half life of response longer than 5 seconds (Fig. 3).

DISCUSSION

From the standpoint of reflex measurement there are thus two properties that are distinctive of the tumour group viz. an elevated reflex threshold and the described abnormally rapid decay in the reflex response.

As regards unilateral elevation of the reflex threshold, this sign is not exclusively pathognomonic of retrocochlear lesions of this particular type. Although very rarely encountered, such elevation may be observed for example in certain forms of sudden deafness. It is thus evident that even though a unilateral pathological elevation of the reflex threshold is not entirely specific for expansive lesions involving the acoustic nerve it should always arouse suspicion of the presence of such a lesion.

Fig. 4 Audiograms in two cases of retrocochlear lesion showing how reflex-threshold elevation may appear independently of hearing-threshold elevation.
 Left audiogram: Woman, 23 years, with surgically confirmed tumour of the left posterior fossa.
 Right audiogram: Man, 67 years, with surgically confirmed acoustic tumour on the right side.
 Continuous curve is hearing threshold, reflex threshold dash-dotted with normal range shaded. In both cases, hearing and reflex threshold were within normal limits in the opposite ear.

In this context, it is also important to discuss the seven cases in which no reflex response was obtained despite maximal acoustic stimulation. It was established in every case that the lack of reflex responses not merely depended on a conductive defect in the recording ear which prevented recording. As reflex responses of normal characteristics could be obtained by tactile or electrical stimulation, the possibility of a conductive defect in the recording ear could be ruled out.

In the cases in which the reflex threshold could be reached, the reflex threshold curves were fairly similar sloping from 125 cps and generally exceeding the working range of the audiometer at 1000 or 1500 cps. Even if no direct parallelism was present between the degree of hearing-threshold loss and elevation of the reflex threshold (Fig. 4) the tendency was nevertheless distinct. Thus, of the 10 cases in which the reflex threshold could still be reached, no less than six were found in the group with a hearing threshold of 20 dB or better.

During the years that this study has been going on, the reflex-decay test has been per-

formed in more than 600 patients in whom the clinical picture pointed to the possibility of a retrocochlear lesion, i.e., the greater part of the patients referred to our department for thorough otoneurological examination. In this biased case material of sensory defects in which a disproportionate number of retrocochlear lesions would be expected, only six additional cases of definitely pathological reflex decay were found. In none of these, however did the further medical examination disclose any signs of an expansive lesion. In these six cases, the traditional differential-diagnostic hearing tests were indicative of retrocochlear hearing impairment in two thirds of the applications, i.e. a slightly higher proportion than in the group of verified tumours. There can be hardly any doubt that these patients also suffered from some form of impairment of the acoustic nerve although it was of a less specific nature.

A natural question in this connection is whether the cause of this fatigue is to be sought in the motor or sensory part of the reflex arc. The very fact that the reflex decay is dependent on the stimulus frequency suggests that the fatigue lies on the afferent side. Moreover

The results of the traditional hearing tests used in differential diagnosis, namely speech discrimination, Fowler's test and the hearing threshold decay test, are found in Table 1. These tests were positive in only about 50 per cent of the applications, a degree of unreliability that is a well-documented feature.

As regards the results of the reflex measurements the reflex threshold was pathologically elevated in all 17 cases. In seven cases so much that the reflex could not be elicited even at maximum available sound stimulus (120 dB hearing level).

In the 10 cases in which the reflex threshold could be attained however there was yet another interesting feature in the reflex response viz. an abnormally rapid fatigue on prolonged stimulation. As has previously been shown there is normally no measurable reflex decay for the frequencies 500 and 1000 cps. For the tumour group there was a marked reflex decay: the response amplitude for these frequencies being halved in about 3 seconds

CASE H S

Fig. 3 Recording of reflex decay in one of the acoustic-tumour cases. In the left, normal ear no reflex decay is observed, and the response has here the characteristic rectangular configuration. In the affected right ear the reflex decay is clearly seen: the half life of response (indicated by arrows) is of the order of 4 seconds.

in none of the subjects. In any of the test frequencies, was the half-life of response longer than 5 seconds (Fig. 3).

DISCUSSION

From the standpoint of reflex measurement there are thus two properties that are distinctive of the tumour group, viz. an elevated reflex threshold and the described abnormally rapid decay in the reflex response.

As regards unilateral elevation of the reflex threshold, this sign is not exclusively pathognomonic of retrocochlear lesions of this particular type. Although very rarely encountered such elevation may be observed for example in certain forms of "sudden deafness". It is thus evident that even though a unilateral pathological elevation of the reflex threshold is not entirely specific for expansive lesions involving the acoustic nerve it should always arouse suspicion of the presence of such a lesion.

this is readily confirmed experimentally. For even in the fatigue phase the full amplitude of the response is readily recovered by inserting complementary acoustic or tactile stimuli.

Naturally more moderate degrees of reflex decay are occasionally encountered which, according to these primary criteria, cannot be classified as pathological in today's situation. Nevertheless, such cases merit considerable interest for future studies. This is especially true because recent research had confirmed that histologically demonstrable lesions of the acoustic nerve (including acoustic tumours) are far more common than can be inferred from their clinical manifestations, as revealed by the traditional audiometric tests (Moberg *et al.* 1969).

When using the reflex-decay test as a diagnostic tool, it must be borne in mind that the present investigations were made in cases of moderate hearing loss, i.e. not exceeding 60 dB. As regards extremely severe hearing impairment, cases of pathological reflex decay may occasionally be found in which it is not necessary or even reasonable to suspect the existence of an expansive lesion. This seems to be completely reasonable since such severe damage, even if it is primarily of hair-cell origin, would also be likely to lead to retrograde degenerative processes.

In contrast to the sensitivity of the reflex test in demonstrating a retrocochlear lesion we have the results of the customary psycho-acoustic differential-diagnostic tests. Here we note a remarkably low score, despite the fact that the demands were very moderate for a result to be regarded as positive. Thus, for a positive outcome in the Fowler test, only an imbalance of 15 dB or more was required (at 500 1000 and 2000 cps or of these applicable test frequencies). In the threshold decay test, the corresponding requirement was a threshold shift of more than 25 dB (at 2000 cps or the nearest lower applicable test frequency). The speech-discrimination test was evaluated only on the basis of experience from the position and shape of the hearing threshold curve. Although the number of positive results of these

three traditional tests increases with the degree of hearing-threshold impairment, the scatter is great and the deviations numerous.

From a general medical standpoint, the detection of retrocochlear disorder is obviously of the greatest importance. This is so because this hearing defect differs in a dramatic way from all other forms in that it indicates the possible existence of a lesion which, without surgical measures, is generally directly life-threatening. By means of the described relatively simple clinical test we are now able to screen out the very few possible tumour cases from the relatively large group of suspected cases. Moreover the reflex test has proved to be sensitive enough to identify these lesions at a very early stage. The importance of this possibility can scarcely be overestimated as early diagnosis is a prerequisite for a lenient surgical technique and a better prognosis (House, 1964; Fluor & Steiner 1969).

CLINICAL "ELECTRICAL RESPONSE AUDIOMETRY" ON
A GENERAL-PURPOSE COMPUTER (IBM 1800)

G Salomon

*From the Department of Otolaryngology and the Department for Data Processing in
Medicine Copenhagen County Hospital Gentofte Denmark*

A computer programme permitting the use of a general-purpose computer (IBM 1800) in evoked response audiometry has been developed. A DC coupling of the computer is obtained by digital parallel displacement of the sampling sweeps. EEG amplitudes (RMS) are calculated before and after stimulation. The V potentials in babies are facilitated by this DC coupling. In addition to the V potentials, a reduction in the EEG amplitude in response to sound indicates sound perception.

Evoked response audiometry (ERA) is often difficult in children. The V potential varies partly due to movement artifacts partly because the response has an uncharacteristic shape. The electronegative component N_{100} at a latency of 100 msec. and the P_{200} are often not prominent. On the other hand, the late positive components with long duration are marked. To facilitate the presentation of the slow positive components a DC recording system with time constants of 3-10 sec. would be desirable.

In EEG audiometry any reproducible change in the EEG in response to sound stimulation indicates sound perception (Derbyshire 1964). Thus, our general-purpose computer programme (Skogstad Nielsen *et al* 1970) has been designed to calculate simultaneously both the usual summation and the amplitude of the EEG (RMS) during the sampling time.

THE DC PROBLEM

Our analogue to digital converter (ADC) will digitalize values between ± 5 volts into $\pm 32,000$ digits.

We found that a DC-coupled EEG amplifier with a gain of 10 000 rarely exceeded these limits and mostly gave AC components of approx 250 mV. As the EEG recording was performed with 1% accuracy and as 250 mV on our ADC gave 400 digits, we normally divided our digital values by 4. In a few patients larger DC changes occurred. This was overcome by decreasing the EEG-amplifier gain by a factor 2 or 4 and dividing the digital values by a correspondingly smaller number.

Fig. 1 shows schematically an EEG recorded with a time constant of 10 sec. S_1 , S_4 , S_7 are sampling sweeps to be summated. Due to the DC recording these sampling sweeps have a mean deviation of (MD) volts from 0 volt. If 150 measuring points are used for digitalization of each sampled sweep, the mean deviation

$$(MD) = \frac{\sum_{i=1}^{150} a_i}{150}$$

If this deviation is subtracted from each measured value in the S_1 sweep a parallel displacement of the S_1 sweep is obtained. A similar parallel displacement is performed in all sweeps. During further calculations the values of a_1 , a_4 , a_{10} are replaced by the corrected values $(a_1 - MD)$, $(a_4 - MD)$, $(a_{10} - MD)$. The value $(a_1 - MD)$ is indicated by a_{11} . The member in the n th sweep is indicated by a_n . If we still use 150 measuring points, and if we call the total number of stimuli

CLINICAL "ELECTRICAL RESPONSE AUDIOMETRY" ON A GENERAL PURPOSE COMPUTER (IBM 1800)

G Salomon

*From the Department of Otolaryngology and the Department for Data Processing in
Medicine Copenhagen County Hospital Gentofte Denmark*

A computer programme permitting the use of a general-purpose computer (IBM 1800) in evoked response audiometry has been developed. A DC coupling of the computer is obtained by digital parallel displacement of the sampling sweeps. EEG amplitudes (RMS) are calculated before and after stimulation. The V potentials in babies are facilitated by this DC coupling. In addition to the V potentials, a reduction in the EEG amplitude in response to sound indicates sound perception.

Evoked response audiometry (ERA) is often difficult in children. The V potential varies partly due to movement artifacts, partly because the response has an uncharacteristic shape. The electronegative component N₁₀₀ at a latency of 100 msec. and the P₂₀₀ are often not prominent. On the other hand, the late positive components with long duration are marked. To facilitate the presentation of the slow positive components a DC recording system with time constants of 3-10 sec. would be desirable.

In EEG audiometry any reproducible change in the EEG in response to sound stimulation indicates sound perception (Derbyshire, 1964). Thus, our general purpose computer programme (Slogstad Nielsen *et al* 1970) has been designed to calculate simultaneously both the usual summation and the amplitude of the EEG (RMS) during the sampling time.

THE DC PROBLEM

Our analogue to digital converter (ADC) will digitalize values between ± 5 volts into $\pm 32\ 000$ digits.

We found that a DC-coupled EEG amplifier with a gain of 10 000 rarely exceeded these limits and mostly gave AC components of approx. 250 mV. As the EEG recording was performed with 1% accuracy and as 250 mV on our ADC gave 400 digits, we normally divided our digital values by 4. In a few patients larger DC changes occurred. This was overcome by decreasing the EEG-amplifier gain by a factor 2 or 4 and dividing the digital values by a correspondingly smaller number.

Fig. 1 shows schematically an EEG recorded with a time constant of 10 sec. S₁, S₂, S₃ are sampling sweeps to be summated. Due to the DC recording these sampling sweeps have a mean deviation of (MD) volts from 0 volt. If 150 measuring points are used for digitalization of each sampled sweep the mean deviation

$$(MD) \text{ is } \frac{\sum_{i=1}^{150} a_i}{150}$$

If this deviation is subtracted from each measured value in the S₁ sweep a parallel displacement of the S₁ sweep is obtained. A similar parallel displacement is performed in all sweeps. During further calculations the values of a₁, a₂, ..., a₁₅₀ are replaced by the corrected values (a₁ - MD), (a₂ - MD), (a₁₅₀ - MD). The value (a₁ - MD) is indicated by a₁. The member in the nth sweep is indicated by a_n. If we still use 150 measuring points, and if we call the total number of stimuli

Fig. 1.

N, we accumulate the following values in the core memory

$$1) \sum_{n=1}^N S_{1,n} \quad \sum_{n=1}^N S_{82,n} \quad \sum_{n=1}^N S_{180,n}$$

$$2) \sum_{n=1}^N (S_{1,n})^2 \quad \sum_{n=1}^N (S_{82,n})^2 \quad \sum_{n=1}^N (S_{180,n})^2$$

During the interval between stimuli we calculate the means, for instance Mean of the 82

addresses, $M_{82} = \frac{\sum_{n=1}^N S_{82,n}}{N}$ and these values are

played on the oscilloscope screen on line.

EVALUATION OF EEG AMPLITUDE

The voltage measured in, for instance, the 82nd measuring point is different after each stimulus. We have chosen the RMS values of this fluctuating voltage to represent the EEG amplitude of this measuring point, and the RMS value is calculated in every address using this formula (N indicating the total number of sweeps)

$$RMS_{82,n} = \sqrt{\frac{\sum_{n=1}^N (S_{82,n})^2}{N} - (M_{82,n})^2}$$

Fig. 2 shows the display obtained. The RMS value is purely numerical. The two mirrored curves on both sides of the X axis indicate the

Fig. 2.

Fig. 3 Summated curves (fat line) and RMS curves in response to sound stimuli (arrow). Left, from a 7-week-old baby; right, from a 3-month-old baby.

RMS values While the upper part of the figure is drawn schematically the lower curves are obtained from a normal adult person.

RESULTS

The lower part of Fig. 2 shows a V potential (fat curve) in response to a sound stimulus (arrow) and one of the curves through the RMS values. We have found two types of changes in the RMS value in response to sound stimulus.

Type 1 occurs when the components of the V potential are large, as compared with the running EEG, thus augmenting the RMS value of the EEG. Note the bump opposite N¹.

Type 2 representation of sound perception is present when a decrease in EEG amplitude is demonstrated on the RMS curve.

After sound application (arrow) the curve is arch-shaped showing a transient decrease in EEG amplitude.

Fig. 3 shows curves obtained from two different children. The summated curves to the left from a baby only a few weeks old show at about 140 msec. a sudden change from negative to positive values. (N¹) followed by a nearly square-wave-shaped curve. We have often seen a small positive peak in the middle of the square wave. A very similar response pattern is shown to the right. It is from a 3-month-old baby. The baby to the left showed a very marked type 2 pattern of the RMS curve.

Twenty severely deaf psychiatric male and female patients in whom conventional audiometry was uncertain were tested with ERA. The average age was 34 years. Only one patient had clinical anacusis, and ERA showed no response. In 13 patients, the average difference in the threshold of 500, 1000 and 2000 cps

Fig. 4 Summated curves in response to sound stimuli (arrow) from two different patients with severe mental disorders.

was 8 dB or less. In four patients, the ERA was 70-30 dB better than conventional, in one 15 dB and in another 30 dB poorer. Thus, we found either a very good correlation or a marked difference between ERA and conventional audiograms. In the V potentials from the patients with severe mental disorders we often found a marked resemblance of the infantile V potentials.

The left and right sides of Fig. 4 show summarized curves from two patients in this group. The N₁ is relatively small or absent, and a DC component is a prominent feature of the response.

DISCUSSION

Krogh. We have stimulated neonates with a high intensity (80-100 dB sensation level) and the response showed P N peaks with a latency period of 400-500 msec. Can you, on the basis of your experience, say whether this might be an evoked response from a tactile stimulation?

G Salomon (Reply to Krogh) I think the late positive component was elicited in response to sound, as only 50 dB on free field was active in small children.

REGISTRATION OF ACOUSTICALLY EVOKED VERTEX POTENTIALS WITH UNCONVENTIONAL AVERAGING TECHNIQUE

S Harly E. B Neergaard A Harbo O Blegvad Andersen and O Elbrønd

From the Department of Otolaryngology University Hospital Aarhus Denmark

The recording of acoustically evoked EEG potentials is normally considered to be dependent on an electronic average computer. The present paper describes a measuring set up for such registrations without use of a conventional averaging technique. The repetitive signals are displayed on an oscilloscope with a camera attachment supplied with a special lens system. The image obtained by superposition of the individually displayed traces will under appropriate conditions disclose the true average of the received evoked potentials. Some examples are given to illustrate the clinical applicability of the method.

The applicability of recordings of the vertex potential in hearing tests relies on repetitive measurements. The faint voltage variations produced by weak acoustic stimuli are concealed by the spontaneous activity known as the EEG. The customary procedure to disclose the acoustically evoked potentials involves an electronic computer to calculate the average response to a series of identical stimuli.

A simple presentation of several signals may be recorded as superimposed traces on an ordinary oscilloscope with a camera attachment. These superimposed traces, although occasionally disclosing the response do not abolish the need for an average recording. It is, however possible to modify the photographic procedure so that the bundle of individual traces is replaced by a continuous band which may be chosen to reveal the arithmetic mean or the median as desired.

The principle is based on a controlled dispersion of the image forming light in the direction of the y-axis. To obtain the arithmetic average a cylinder lens with a suitable rhombic aperture (fig 1) may be used instead of the

ordinary photographic objective. A curve displayed on the oscilloscope will hence produce an image shaped as a band with an illumination falling off linearly towards the edges. The light distribution along a horizontal line through this band will be seen to exhibit intensity variations exactly corresponding to the signal pattern. When more sweeps follow these light distributions will add up and on the photographic film expose the sum of the successive signals along the horizontal line. Owing to the linear slope of the light intensity the true average of all the sweeps will also appear as a curve following an appropriate constant exposure value on the film.

One of the procedures that will produce the necessary light distribution is outlined in Fig. 1. The cylinder lens combined with the rhombic aperture will thus constitute the necessary in-

Fig. 1 Diagram of a system for optical formation of arithmetic mean of traces displayed on an oscilloscope

A

B

Fig. 2. Example of a recording from a normal person, 1, 20 superimposed traces, 2, band representing arithmetic mean of these traces; 3, band representing the median of the same traces. A, without stimulus; B, with stimulus, 1000 Hz, 10 dB above subjectively determined threshold.

struments for the formation of the arithmetic mean. It is, however, only necessary to replace the shown aperture with a rectangular one if it is wanted to obtain the median value instead of the arithmetic mean. The well-known advantage of the median as compared to the arithmetic mean in physiological measurements is the insensitivity to noise peaks. This noise eliminating feature will be further supplemented in any of the described optical procedures because excessively large noise peaks will simply offset the tracing out of the average-forming band.

Our present technique allows the simultaneous recording of (1) all the individual traces, (2) the arithmetic mean, and (3) the median.

Next to these recordings, on the same po-

laroid picture, is a control series (no stimulus) as seen in Fig. 2.

This is the basis of the new optical data processing, but significant extensions including multichannel recording, frequency analysis, pattern recognition and correlation analysis are in development. It should be mentioned that the described average-forming technique may be applied at considerably less costs than currently available electronic computers.

The successful application of the ERA depends on reliable electrode connections to the patient. The necessary low electrode resistance (1000–6000 ohms between two electrodes measured at approx. 100 mV, 500 Hz) appears to be conveniently obtained with skin electrodes of german silver 18 mm dia., and an electrode

Table 1 31 ears (16 persons)

Intensity	< 20 dB	20-30 dB	> 30 dB
Pos. responses	4	3	4

Jelly composed of Elema Mingograph Cream plus a few per cent Bio-Tex (an ordinary enzyme based washing powder)

In order to test the described apparatus for objective assessment of hearing we have examined 40 patients aged from 6 to 37 years.

The method of the examination is as follows. The patients are examined awake lying on a couch in a sound-proof room. They are asked to count the number of sound stimuli used. After washing of the skin the electrodes are fixed by means of the above mentioned electrode paste and tape.

During the first period vertex frontal recording was used. The placing of the electrodes is now in accordance with the standard potentials being recorded between the vertex and the left mastoid.

The resistance between the electrodes is measured in each investigation. We have in all cases, if necessary repositioning the electrodes, achieved a resistance below 6000 ohms, and in 12 cases we have found values below 2000 ohms. In order to obtain a significant response it is of great importance to achieve the lowest possible resistance.

Previous to the examination the hearing level of the patient is determined in the conventional manner.

The stimulus used is a pure tone of 1000 Hz with approx. 25 msec. onset and of 500 msec. duration. The tone is applied at 10-second interval and is repeated 20 times. The

patient is stimulated monaurally and the traces on the oscilloscope are photographed. On the same picture 20 sweeps without stimulating the patients are recorded as a control.

Our series consists of 40 persons, aged from 6 to 37 years, with normal hearing in whom 78 ears were examined. In the first group of the series, potentials were recorded between the vertex and the frontal region. In the second group recording was made between the vertex and the mastoid. In group 1 (16 persons 31 ears) significant evoked responses were obtained in 24 cases after stimulation up to 30 dB above the hearing level. Intensities between 20-30 dB produced response in three cases. No significant evoked response was obtained in four cases, but it must be added that in these cases stimuli exceeding 30 dB were not used (Table 1).

Group 2 comprised 24 persons (47 ears). Only stimuli of 10 dB above the thresholds were used in this group. Table 2 shows that in no less than 43 out of 47 ears a positive response was elicited, and that no response was obtained in four cases (Table 2).

The clinical importance of this method can be illustrated by the following case of psychogenic deafness.

A 21 year old soldier complained after shooting of total deafness in the left ear. He had been examined several times with reference to his loss of hearing, which was interpreted as real. With a view to the claim for compensation the patient was again referred to examination. Pure-tone audiometry showed continuously no hearing in the left ear. Evoked-response audiometry produced significant responses from both ears when stimuli of 15 dB above normal hearing level was used. The examination was carried out only at 1000 Hz. The stapedius reflexes of the patient were examined and found normal in both ears with homolateral as well as contralateral stimulation. Hence this examination confirms the hearing threshold of the patient as obtained by means of the EEG audiometry.

This method of optical average recording in electrical response audiometry has been used only for a short period, and only a few patients have been examined. Though based on a limited experience it is indicated that instrumentation of this type will prove valuable in future clinical investigations.

EVOKED RESPONSES TO SISI STIMULI CONTRALATERAL MASKING EFFECTS

P. Osterhammel, K. Terkildsen and P. Arndal

From the Department of Otolaryngology the University Hospital, Copenhagen, Denmark

Evoked cortical responses to Sisi-type stimuli at 20-dB sensation level and increment magnitudes 2, 3 and 5 dB tend to be enhanced by the application of contralateral masking noise. With 5 dB increments and the continuous tone at the threshold of hearing the same masking noise caused the response to disappear. The enhancement of auditory discrimination at suprathreshold levels through application of contralateral masking and the "central masking effect" at the threshold are thought to be comparable to the so-called indirect adaptation mechanism of the eye and as indication that the efferent innervation to the cochlea is important for the adaptation of the ear.

In the field of sensory physiology the phenomenon of adaptation was first demonstrated for the sense of vision. It was shown that as an integral part of this process adaptation to strong light would at the same time cause a reduced sensitivity to faint light and an elevation of the threshold for light perception.

Investigations on the sense of hearing has primarily been concerned with this negative side of adaptation in the form of changing loudness function and the widely used tone-decay tests.

The positive aspects of adaptation become apparent when contrast thresholds are determined. An adapted eye possesses a better discrimination and more just noticeable differences (JNDs) within the dynamic range to which it is adapted.

The so-called direct adaptation is caused by light which strikes those parts of the retina that are tested. This is different from indirect adaptation, where the performance in the test area is influenced by light that illuminates

other parts of the retina, and thus involves neural mechanisms.

In audiology the Jerger SISI test represents an analogy to direct adaptation. The ear is exposed to a constant tone, and the ability to differentiate is measured by the number of increments which the patient can detect. It is a measurement for difference limen of intensity (DLI) in the adapted state.

Bjergvad and Terkildsen (1967) showed that contralateral masking would improve the DLI in the middle and high-frequency range, when it was measured by this method. Here we apparently have an analogy to the indirect adaptation of the eye. In order to attain a sufficient degree of accuracy in these investigations the statistical threshold function was determined by means of psychometric curves.

The detection of evoked slow cortical potentials as a response to sensory stimuli has opened up interesting possibilities of objective comparisons of the very magnitude of sensory perceptions, instead of being limited to determinations of the threshold. In the present investigation, we measured the cortical response to tone increments and how this response would be influenced by contralateral masking.

The equipment for measuring the slow evoked potentials was based on a Moemotron CAT computer with 400 channels. The EEG electrodes were made of German silver with a 6 cm² electrode area. Electrode placement vertex/mastoid process and ground to the other mastoid process. Amplification 100 000 times

In order to test the described apparatus for objective assessment of hearing we have examined 40 patients aged from 6 to 37 years

The method of the examination is as follows. The patients are examined awake lying on a couch in a sound-proof room. They are asked to count the number of sound stimuli used. After washing of the skin the electrodes are fixed by means of the above mentioned electrode paste and tape.

During the first period vertex frontal recording was used. The placing of the electrodes is now in accordance with the standard, the potentials being recorded between the vertex and the left mastoid.

The resistance between the electrodes is measured in each investigation. We have in all cases, if necessary repositioning the electrodes, achieved a resistance below 6000 ohms, and in 12 cases we have found values below 2000 ohms. In order to obtain a significant response it is of great importance to achieve the lowest possible resistance.

Previous to the examination the hearing level of the patient is determined in the conventional manner.

The stimulus used is a pure tone of 1000 Hz with approx. 25 msec. onset and of 500 msec duration. The tone is applied at 10-second interval and is repeated 20 times. The

patient is stimulated monaurally and the traces on the oscilloscope are photographed. On the same picture 20 sweeps without stimulating the patients are recorded as a control.

Our series consists of 40 persons, aged from 6 to 37 years, with normal hearing in whom 78 ears were examined. In the first group of the series, potentials were recorded between the vertex and the frontal region. In the second group recording was made between the vertex and the mastoid. In group 1 (16 persons 31 ears) significant evoked responses were obtained in 24 cases after stimulation up to 70 dB above the hearing level. Intensities between 20-30 dB produced response in three cases. No significant evoked response was obtained in four cases, but it must be added that in these cases stimuli exceeding 30 dB were not used (Table 1).

Group 2 comprised 24 persons (47 ears). Only stimuli of 10 dB above the thresholds were used in this group. Table 2 shows that in no less than 43 out of 47 ears a positive response was elicited, and that no response was obtained in four cases (Table 2).

The clinical importance of this method can be illustrated by the following case of psychogenic deafness.

A 21 year old soldier complained after shooting of total deafness in the left ear. He had been examined several times with reference to his loss of hearing, which was interpreted as real. With a view to the claim for compensation the patient was again referred to examination. Pure-tone audiometry showed continuously no hearing in the left ear. Evoked-response audiometry produced significant responses from both ears when stimuli of 15 dB above normal hearing level was used. The examination was carried out only at 1000 Hz. The stapedius reflexes of the patient were examined and found normal in both ears with bone as well as contralateral stimulation. Hence this examination confirms the hearing threshold of the patient as obtained by means of the EEG audiometry.

This method of optical average recording in electrical response audiometry has been used only for a short period, and only a few patients have been examined. Though based on a limited experience, it is indicated that instrumentation of this type will prove valuable in future clinical investigations.

EVOKED RESPONSES TO SISI STIMULI

CONTRALATERAL MASKING EFFECTS

P. Osterhammel, K. Terkildsen and P. Arndal

From the Department of Otolaryngology the University Hospital Copenhagen Denmark

Evoked cortical responses to Sisi-type stimuli at 20-dB sensation level and increment magnitudes 2, 3 and 5 dB tend to be enhanced by the application of contralateral masking noise. With 5 dB increments and the continuous tone at the threshold of hearing the same masking noise caused the response to disappear. The enhancement of auditory discrimination at suprathreshold levels through application of contralateral masking and the "central masking effect" at the threshold are thought to be comparable to the so-called indirect adaptation mechanism of the eye, and an indication that the efferent innervation to the cochlea is important for the adaptation of the ear

other parts of the retina, and thus involves neural mechanisms.

In audiology the Jerger SISI test represents an analogy to direct adaptation. The ear is exposed to a constant tone, and the ability to differentiate is measured by the number of increments which the patient can detect. It is a measurement for difference limen of intensity (DLI) in the adapted state.

Bjergvad and Terkildsen (1967) showed that contralateral masking would improve the DLI in the middle and high-frequency range, when it was measured by this method. Here we apparently have an analogy to the indirect adaptation of the eye. In order to attain a sufficient degree of accuracy in these investigations the statistical threshold function was determined by means of psychometric curves.

The detection of evoked slow cortical potentials as a response to sensory stimuli has opened up interesting possibilities of objective comparisons of the very magnitude of sensory perceptions, instead of being limited to determinations of the threshold. In the present investigation, we measured the cortical response to tone increments and how this response would be influenced by contralateral masking.

The equipment for measuring the slow evoked potentials was based on a Mnemotron CAT computer with 400 channels. The EEG electrodes were made of German silver with a 6 cm² electrode area. Electrode placement vertex/mastoid process and ground to the other mastoid process. Amplification 100,000 times

In the field of sensory physiology the phenomenon of adaptation was first demonstrated for the sense of vision. It was shown that as an integral part of this process adaptation to strong light would at the same time cause a reduced sensitivity to faint light and an elevation of the threshold for light perception.

Investigations on the sense of hearing has primarily been concerned with this negative side of adaptation in the form of changing loudness function and the widely used noise-decay tests.

The positive aspects of adaptation become apparent when contrast thresholds are determined. An adapted eye possesses a better discrimination and more just noticeable differences (JNDs) within the dynamic range to which it is adapted.

The so-called direct adaptation is caused by light which strikes those parts of the retina that are tested. This is different from indirect adaptation, where the performance in the test area is influenced by light that illuminates

by two amplifiers in series. The pre-amplifier was of the differential type with an input impedance of 100 M-ohms and a high common mode rejection in order to ensure an optimal cancelling of in phase signals. The main amplifier was supplied with various selective filters, amongst others for the line frequency. Frequency range 0.1–30 cps.

The test programme made it necessary to record the whole procedure by means of a DC tape recorder at the same time as the on-line computer averaging. For the write-out we used a X-Y plotter. In order to permit exact measurements, the set-up was supplied with a calibration unit controlled by the X sweep of the computer and on each curve a summated calibration pulse was automatically recorded at the end of the "window". The tones came from a Madsen OB 60 audiometer and the increments were controlled by a photo-electric device (Blegvad 1966). To this was added an extra trigger unit to start the computer and supply the DC recording with pulses necessary for the off line analysis.

The cortical response to strong stimuli is well defined especially with regard to latency. When the stimulus gets close to threshold the response becomes much more variable which is obviously particularly detrimental for work with an averaging technique. In order to reduce this variability we tried to keep the test conditions as constant as possible. The investigation was conducted in a darkened sound proof room. The subject rested in a reclining comfortable chair with support of the neck and the feet.

Evoked responses were recorded for increments of 2, 3 and 5 dB at 20 dB SL and with the frequencies 1000 and 4000 cps. The increments had a duration of 200 msec and rise fall times of 50 msec, as in Jerger's test. In order to shorten the procedure the intervals were only 2.5 sec. The increments were presented in series of 50 and there were a total of 10 such series for each increment magnitude at both frequencies. During every other series, the contralateral ear was exposed to 80 dB

Table 1

	1000 cps			4000 cps

Subject A			++			
Subject B	+		—			
Subject C		+			++	

masking noise. Thus, each measurement is based on a comparison between five series with and five series without contralateral noise. After each series there was an intermission of 2 minutes, during which the averaged response from the computer was recorded.

In order to maintain a steady level of attention the subjects were requested to count the increments.

As already mentioned the procedure was taped by means of a DC recorder. This permitted a separate averaging of all 250 responses with and without contralateral noise.

A programme with 10 series permits a statistical evaluation of the results from each session separately by the Student method. We decided to use a single parameter which included both the response magnitude and the latency. The response magnitude was measured as the difference between N_1 and P_2 in microvolts and divided by the latency to P_2 in msec. As N_1 we would accept the largest negativity in the time area 100 to 230 msec and as P_2 the largest positivity between 180 and 400 msec after stimulus onset.

The results are seen in Table 1 in which + and ++ indicate that the evoked response was larger with contralateral noise and at statistical confidence levels of 5% and 1% respectively. — indicates that, under similar circumstances, the response was smaller at the 5% level.

It should be mentioned that the evoked response to such weak stimuli is relatively small and the signal to noise ratio often unsatisfactory. The results can therefore only be taken as an indication of what actually takes place by the application of contralateral noise. A

more complete description of the function would necessitate much larger series.

The results from counting the increments is only of interest for the 2 dB stimuli, which were at the threshold of audibility. In all instances, the subjects would detect more increments when contralateral noise was present, and there was good agreement between the subjective and objective findings.

It is well known that contralateral noise causes an elevation of the threshold for hearing. This so-called central masking effect was demonstrated objectively in the following way. The constant tone was set at the hearing threshold and the increments at 5 dB. In two of the subjects, these increments evoked a clear cut response, which, however disappeared as soon as contralateral noise was introduced. Al-

so this objective finding corresponded to the subjective listening results.

If we return to the introductory remarks about adaptation of the eye, our findings with regard to the effect of contralateral masking noise appears to be very similar to the so-called indirect adaptation, and this applies both to the improved DLI above threshold as well as the elevation of the threshold itself.

Ever since the anatomical detection of the dense efferent innervation to the organ of Corti, there have been speculations about the psychophysical correlate, or in other words, the meaning of this arrangement. Our findings show that the adaptation level in one ear is partly determined by the other and it seems natural to see this as one function of the efferent innervation.

EEG-COMPUTER AUDIOMETRY (ERA) IN A GROUP OF PRE-SCHOOL AND SCHOOL AGE CHILDREN

H Economopoulou H J Krogh and L Fosvig

*From the Research Laboratory for Technical Audiology of the State Hearing Centres
Odense County and City Hospital Odense Denmark*

A study of average evoked responses in a number of normal, mentally retarded and aphasic pre-school and school children is reported. The purpose was to evaluate this new technique in order to apply it as a possible objective audiometric method in general or in a limited group of children. An averaged evoked response was recorded from the vertex electrode in all the children tested. Comparisons were made between ERA and audiometric thresholds. Our experience leads us to place considerable confidence in electrophysiologically determined threshold measurements.

The description below deals with a study in evoked response audiometry (ERA). The main purpose of this study was to examine the usefulness of the ERA method in general and to compare it with the ordinary audiometry. We were particularly interested in this method for the use in children's audiometry.

Our clinical group consisted of 65 pre school and school age children, viz. 42 boys and 23 girls. Of these 44 were considered normal apart from their hearing impairment. 13 were aphasic of the impressive or expressive type and 8 were mentally retarded.

The ages of the children ranged from 2 to 16 years and averaged 8.3 years. Standard audiograms were available for 44 of the children, and the time which had elapsed from the evaluation of the standard audiogram averaged approx. 4 months.

Electrode Placement

The ongoing EEG activity was picked up by scalp solder-disc electrodes attached to the head with EEG electrode paste and pulverized

pumicestone. In small and restless children the electrodes were held in position with collodium. The signal electrode was placed in the vertex with the mastoid process as reference and the ground electrode was placed frontally.

Before the start of the test the electrode resistance was approx. 1000 ohms, which later increased slightly.

Test Procedure

The measurements were made in a normal audiometry room. The patient was sitting in a comfortable armchair in a reclined position (Fig. 1). Small children were preferably sitting on the mother's lap or they were playing with toys on the floor. Most of the children were remarkably co-operative and quiet throughout the examination. The duration of the test was 1½-2 hours.

Stimuli

The stimuli consisted of non-click tone pulses with frequencies of 500, 1000 and 4000 cps. The total length of the tone pulse was 400 msec with a rise and decay time of 25 msec each. Normally the stimuli were delivered at a rate of one every 3 sec. and each stimulus was presented 100 times. The EEG was monitored on an oscilloscope in order to test the general condition of the patient and the electrodes, after which the evoked signal was fed into the computer (T M I CAT 400 C) and

the first 500 msec. of the response was analysed and then the sum response plotted out on a level recorder (Figs. 2 and 3).

Running

The procedure for establishing the threshold response varied somewhat as the examiner gained experience in the technique. At first we started with a stimulus of high sound intensity to make sure of obtaining a well-defined response, which were significant at the threshold stimulus to the ERA threshold, but during the latter part of the test we discovered some false results, as well as rather poorly defined responses, which were significant at the threshold level, probably due to habituation, fatigue of the patient, and/or drying of the electrode paste. The latter problem was solved by keeping the electrodes moist with the aid of small pieces of rubber sponge. The former was solved by using a somewhat different stimulation procedure. Firstly by giving a high and then a low intensity level. A high intensity of about 80 dB sensation level to give a clear response as a guide to the threshold response. The low intensity must be determined by the experienced examiner. If there is no response from this low intensity then the average of the

Fig. 1 ERA test in seven year old boy sitting in a comfortable armchair playing with toys.

two values should be tried. Should, however the response be positive, then the attenuator should be decreased in 10 dB steps.

In cases where we experienced difficulty in determining the threshold, we found it advantageous to increase the number of stimulations by for instance, 50. This also resulted in minimizing the influence of a high background activity.

The presence or absence of the response was judged "on-line" from the response pattern on the computer display and the new intensity and frequency were selected according to this.

EEG-COMPUTER AUDIOMETRY (ERA) IN A GROUP OF PRE SCHOOL AND SCHOOL AGE CHILDREN

H Economopoulou, H J Krogh and L Fosvig

*From the Research Laboratory for Technical Audiology of the State Hearing Centres
Odense County and City Hospital Odense Denmark*

A study of average evoked responses in a number of normal mentally retarded and aphasic pre school and school children is reported. The purpose was to evaluate this new technique in order to apply it as a possible objective audiometric method in general or in a limited group of children. An averaged evoked response was recorded from the vertex electrode in all the children tested. Comparisons were made between ERA and audiometric thresholds. Our experience leads us to place considerable confidence in electrophysiologically determined threshold measurements.

The description below deals with a study in evoked response audiometry (ERA). The main purpose of this study was to examine the usefulness of the ERA method in general and to compare it with the ordinary audiometry. We were particularly interested in this method for the use in children's audiometry.

Our clinical group consisted of 65 pre-school and school-age children, viz. 42 boys and 23 girls. Of these, 44 were considered normal apart from their hearing impairment. 13 were aphasic of the impulsive or expressive type and 8 were mentally retarded.

The ages of the children ranged from 2 to 16 years and averaged 8.3 years. Standard audiograms were available for 44 of the children, and the time which had elapsed from the evaluation of the standard audiogram averaged approx. 4 months.

Electrode Placement

The ongoing EEG activity was picked up by scalp solder-disc electrodes attached to the head with EEG electrode paste and pulverized

pumicestone. In small and restless children, the electrodes were held in position with collodium. The signal electrode was placed in the vertex with the mastoid process as reference and the ground electrode was placed frontally.

Before the start of the test, the electrode resistance was approx. 1000 ohms, which later increased slightly.

Test Procedure

The measurements were made in a normal audiometry room. The patient was sitting in a comfortable armchair in a reclined position (Fig. 1). Small children were preferably sitting on the mother's lap or they were playing with toys on the floor. Most of the children were remarkably co-operative and quiet throughout the examination. The duration of the test was 1½-2 hours.

Stimuli

The stimuli consisted of non-click tone pulses with frequencies of 500, 1000 and 4000 cps. The total length of the tone pulse was 400 msec with a rise and decay time of 25 msec. each. Normally the stimuli were delivered at a rate of one every 3 sec. and each stimulus was presented 100 times. The EEG was monitored on an oscilloscope in order to test the general condition of the patient and the electrodes, after which the evoked signal was fed into the computer (T M I CAT 400 C) and

the first 500 msec. of the response was analysed and then the sum response plotted out on a level recorder (Figs. 2 and 3)

Recording

The procedure for establishing the threshold response varied somewhat as the examiner gained experience in the technique. At first we started with a stimulus of high sound intensity to make sure of obtaining a well-defined response, which were significant at the threshold stimulus to the ERA threshold, but during the latter part of the test we discovered some false results, as well as rather poorly defined responses, which were significant at the threshold level, probably due to habituation, fatigue of the patient, and/or drying of the electrode paste. The latter problem was solved by keeping the electrodes moist with the aid of small pieces of rubber sponge. The former was solved by using a somewhat different stimulation procedure. Firstly by giving a high and then a low intensity level. A high intensity of about 80 dB sensation level to give a clear response as a guide to the threshold response. The low intensity must be determined by the experienced examiner. If there is no response from this low intensity then the average of the

Fig. 1 ERA test in a seven year old boy sitting in comfortable armchair playing with toys.

two values should be tried. Should, however the response be positive, then the attenuator should be decreased in 10 dB steps.

In cases where we experienced difficulty in determining the threshold, we found it advantageous to increase the number of stimulations by for instance, 50. This also resulted in minimizing the influence of a high background activity.

The presence or absence of the response was judged "on-line" from the response pattern on the computer display and the new intensity and frequency were selected according to this.

Fig. 2. The tone pulse is delivered to the patient's ear. Below left, the evoked response with the noisy background activity right, the averaged evoked response after 100 shots.

Fig. 3 Principle diagram of the apparatus used for the ERA test.

RESULTS

The recordings were mainly analysed for the purpose of deciding the ERA threshold. This was determined as follows: That pulse tone in intensity which showed response whereas a pulse tone of 5 dB lower intensity did not. All the 65 children examined showed characteristic responses. This was defined as a three phasic wave form which started with a positive deflection or peak P_1 at about 100 msec. after the start of the stimulus, a negative, N_1 at about 150 msec. and another positive P_2 at about 250 msec.

By comparing the individual recordings we found small deviations from person to person, and sometimes also from the first to the last recorded response at the same intensity and in the same person.

Special attention was paid to the evaluation of the responses elicited in mentally retarded and aphasic children for the purpose of disclosing possible significant variations from normal but there were no large differences in the three groups.

It was ascertained that a reduction in the

stimulus intensity resulted in a decrease in the response amplitude and an increase of the latency time. The threshold response may occasionally be somewhat uncertain and in such cases it will be necessary to compare this with an evoked response of high intensity together with a display of the background activity. If this is fairly high it may be necessary to increase the number of stimuli.

A few of the children were rather restless during the test but nevertheless we obtained responses. In these particular cases, the major problem was to fasten the electrodes and to place the telephone. In some cases, we decided to use a free field signal. With reasonable probability we obtained responses in 51 children at three frequencies, in 12 children at two frequencies, and in two children at one frequency. The absence of response was due to the threshold being beyond the measuring range of the audiometer or due to lack of time and to the presence of a high background activity.

Comparison between the ERA threshold and the standard audiometric threshold obtained for the same ear showed a mean difference of 2 dB (ERA minus normal values).

Conclusion

This preliminary investigation indicated that ERA will be a useful instrument for the examination of the human hearing in unco-operative cases. At the same time we have a remedy in the differential diagnosis between deafness and aphasia. However it must be noted that the ERA method on account of the relatively long examination time required is only justified in special cases in which normal methods cannot be used with advantage.

Finally we may remark that a tool has been placed into our hands which opens up the possibility of investigating part of the hearing mechanism even in neonates. This is of great significance especially for children in the risk group.

EVOKED-RESPONSE AUDIOMETRY

S. C. Dalsgaard

*From the Research Laboratory for Technical Audiology / the State Hearing Centres
Odense County and City Hospital, Odense, Denmark*

Within the last decade, evoked-response audiometry (ERA), based on recording of acoustically evoked cortical potentials, has become increasingly common in the audiological clinic. This technique, however, need still be considered to be at the experimental stage, and it is at present difficult to foresee the advances which the use of this method will introduce into audiological work.

In this technique, it is important, before the test is undertaken, to take the following questions into account: What is the purpose of the test? What use is going to be made of its results? A test should not be performed simply for the sake of prestige. The more complicated an investigation is, the more important is the assessment of the expected results.

After an analysis of the scope and purpose, the method should be adjusted in accordance with the expected usefulness. From a technical point of view it must be considered irrational to carry out a series of complicated and time consuming investigations which exhaust both the patient and the examiner if there is not a reasonable possibility that the results of the test can provide data with a bearing on the therapy.

ERA is complicated by the weakness of the evoked potentials, as compared with the general electrical activity of the brain and the muscles. We may regard this activity as a strong background noise which interferes with the measurements, and which it is necessary to suppress in order to determine the evoked potential. This is commonly done by the special computer technique of averaging the re-

sults of several repeated tests. The background noise can be considered random in nature and will by this method approach zero, whereas the evoked potential will increase. After for example, 100 repetitions, the signal-to-noise ratio will theoretically have improved by 20 dB.

The presence of the background noise will introduce a factor of uncertainty in the determination of the evoked potential. For the acquisition of a greater accuracy in our knowledge of this potential a better signal-to-noise ratio and, hence a larger number of repetitions are required. It is not uncommon to use 50-100 repetitions, and as experience shows that the interval between the applications of stimuli must be at least 3 seconds, the ERA test requires a considerable period of time, which is one of the greatest disadvantages of the method.

It is most probable that a detailed knowledge of the evoked potential as a function of time will enable us to obtain information of importance in diagnosis, and that the determination of the response amplitude as a function of the stimulus intensity may reveal further information as to the normal and pathological functions of the sense of hearing. However the present experience in this field is limited, but a great amount of work and ingenuity is devoted to research into the problems involved.

At the present time, ERA is most commonly used in audiological work in order to reveal whether a patient responds to an acoustical

stimulus or not, thus making it possible to record audiograms in unco-operative subjects, such as children mentally retarded patients and malingers. This reduced scope may result in several advantages, because it is unnecessary to obtain a detailed record of the evoked potential as a function of time the only necessity being a determination whether a response is present or not. This can be done with fewer repetitions, especially when the measurements are performed by a trained and experienced examiner.

Furthermore it must be expected that an increase in the signal to-noise ratio can be accomplished by electrical filtering of the recorded signals. This will obviously introduce a linear distortion of the recorded signals, but this is of minor importance in the determination of the presence or absence of response. It should therefore be permissible to reduce the number of repetitions and thus save time.

In the investigations which are carried out at present in co-operation with the Institute for Mental Defectives for South East Jutland at Brejning and the State Hearing Rehabilitation Centre in Odense we have chosen to use the evoked potential merely as an indicator of response or non-response to an acoustical sig-

nal. So far our experience shows that ERA seems to be a useful supplement to the classical audiometric methods. On the other hand, the latter methods give when practicable, much quicker and not less accurate results than ERA. In particular ERA has proved very useful in completely unco-operative subjects and has made it possible to determine the hearing acuity in patients with severe mental defects, which has so far been impossible by the classical methods of audiology.

In providing the equipment for this new audiology it should be kept in mind whether the object is to carry out detailed and accurate studies of the cortical response—which is of great scientific interest, but still of limited clinical value—or just to use the technique as a supplement to existing audiometric methods. In my opinion, the latter object is at present the most profitable and also covers the most urgent demand. The equipment needed for this purpose is less complicated and hence less expensive and it will probably be possible to reduce the time required for the test by further technical improvements. Great efforts are made in several institutions in order to achieve this aim.

THERE IS

AN 

HEARING AID

FOR EVERY TYPE OF

HEARING LOSS

Accurate diagnosis with the B & K Stroboscope Type 4910

It is possible to visually freeze the movement of the larynx at any point in its periodic oscillation and to obtain a continuous slow-motion effect of the vocal chord movement at any frequency. Stroboscopic observation is a valuable aid to an early detection of larynx cancer, recurrent nerve paralysis and tumors, even when they are situated on the lower side of the vocal chords.

A. EINLEITUNG

Mit der Entdeckung des Penicillins durch Fleming trat eine entscheidende Wende in der Behandlung der Infektionskrankheiten ein. Es eröffneten sich der Therapie bis dahin ungeahnte Möglichkeiten. Die Isolierung des Streptomycins im Jahre 1943 durch Wakaman versprach ein weiterer großer therapeutischer Fortschritt zu werden. Das relativ schmale antibakterielle Spektrum des Penicillins fand durch Streptomycin eine wesentliche Verbreiterung. Penicillin und Streptomycin ergänzten sich in geradezu idealer Weise. Mit Recht wird ihre Kombination als das erste antibakterielle Breitbandpräparat bezeichnet. Darüberhinaus war Streptomycin auch das erste und bis heute unübertroffene Antibiotikum, das mit Erfolg gegen die größte Geißel der Menschheit, gegen die Tuberkulose eingesetzt werden konnte.

Umsoweniger folgeschwerer war daher im Jahre 1943 die Nachricht von Hirschman und Feldmann über die toxische Wirkung dieser Substanz auf das cochleovestibuläre System. Die Toxizität dieses neuen Antibiotikums überraschte umso mehr, als man gerade erst im Penicillin ein Medikament mit ungewöhnlich günstiger therapeutischer Breite kennengelernt hat. Die Verwendung des Streptomycins wurde auf Grund dieser Eigenschaft erheblich eingeschränkt. Bis heute kann aber auf dieses wertvolle Antibiotikum zur Bekämpfung der Tuberkulose und anderer Infektionen mit gramnegativen Erregern insbesondere bei bestimmten Endocarditisformen nicht verzichtet werden. Zwar gelang es im Laufe der Zeit durch vorsichtiger und genauere auf den Patienten individuell abgestimmte Dosierungen die toxischen Nebenwirkungen wesentlich herabzusetzen, ohne sie aber ganz beseitigen zu können. Der Arzt steht sich daher immer wieder vor die verantwortungsvolle Aufgabe gestellt dieses Antibiotikum trotz seiner Gefahren weiter anzuwenden.

Ähnlich verhält es sich mit allen anderen zur Aminoglykosidgruppe gehörenden Antibiotika, wie Neomycin, Kanamycin, Paromomycin, Framycetin, Gentamycin und einigen weniger bekannten Verbindungen, die in der Folgezeit entwickelt wurden. Sie sind nicht nur chemisch miteinander verwandt, sondern weisen auch sehr ähnliche ototoxische Eigenschaften wie Streptomycin auf. Ihre Toxizität ist sogar noch wesentlich stärker, sodaß ihre therapeutische Anwendung erst recht in Frage gestellt wird bzw. überwiegend auf eine äußerliche Applikation beschränkt bleiben muß. Durch ihre starken antibakteriellen Eigenschaften und das außergewöhnlich günstige antibakterielle Spektrum würden diese Substanzen sonst eine noch viel größere therapeutische Bedeutung erlangt haben, als es ohnehin schon der

Mit der Entdeckung des Penicillins durch Fleming trat eine entscheidende Wende in der Behandlung der Infektionskrankheiten ein. Es eröffneten sich der Therapie bis dahin ungeahnte Möglichkeiten. Die Isolierung des Streptomycins im Jahre 1943 durch Wakaman versprach ein weiterer großer therapeutischer Fortschritt zu werden. Das relativ schmale antibakterielle Spektrum des Penicillins fand durch Streptomycin eine wesentliche Verbreiterung. Penicillin und Streptomycin ergänzten sich in geradezu idealer Weise. Mit Recht wird ihre Kombination als das erste antibakterielle Breitbandpräparat bezeichnet. Darüberhinaus war Streptomycin auch das erste und bis heute unübertroffene Antibiotikum, das mit Erfolg gegen die größte Geißel der Menschheit, gegen die Tuberkulose eingesetzt werden konnte.

Umso furchtbarer war daher im Jahre 1945 die Nachricht von Hinshaw und Feldmann über die toxische Wirkung dieser Substanz auf das cochleovestibuläre System. Die Toxizität dieses neuen Antibiotikums überraschte umso mehr, als man gerade erst im Penicillin ein Medikament mit ungewöhnlich günstiger therapeutischer Breite kennengelernt hat. Die Verwendung des Streptomycins wurde auf Grund dieser Eigenschaft erheblich eingeschränkt. Bis heute kann aber auf dieses wertvolle Antibiotikum zur Bekämpfung der Tuberkulose und anderer Infektionen mit gramnegativen Erregern insbesondere bei bestimmten Endocarditisformen nicht verzichtet werden. Zwar gelang es im Laufe der Zeit durch vorsichtigeren und genaueren auf den Patienten individuell abgestimmten Dosierungen die toxischen Nebenwirkungen wesentlich herabzusetzen, ohne sie aber ganz beseitigen zu können. Der Arzt sieht sich daher immer wieder vor die verantwortungsvolle Aufgabe gestellt, dieses Antibiotikum trotz seiner Gefahren weiter anzuwenden.

Ähnlich verhält es sich mit allen anderen zur Aminoglykosidgruppe gehörenden Antibiotika, wie Neomycin, Kanamycin, Paromomycin, Framycellin, Gentamycin und einigen weniger bekannten Verbindungen, die in der Folgezeit entwickelt wurden. Sie sind nicht nur chemisch miteinander verwandt, sondern weisen auch sehr ähnliche ototoxische Eigenschaften wie Streptomycin auf. Ihre Toxizität ist sogar noch wesentlich stärker, so daß ihre therapeutische Anwendung erst recht in Frage gestellt wird bzw. überwiegend auf eine äußerliche Applikation beschränkt bleiben muß. Durch ihre starken antibakteriellen Eigenschaften und das außergewöhnlich günstige antibakterielle Spektrum würden diese Substanzen sonst eine noch viel größere therapeutische Bedeutung erlangt haben, als es ohnehin schon der

zuleiten. Darüber hinaus dient sie nach der heute vorherrschenden Meinung den Sinnesepithelien, die keine eigene Blutversorgung besitzen, als Ernährungsmedium.

Die Bedeutung der Endolymphe für die Substrat- und O_2 -Versorgung unterstreichen u. a. auch die jüngsten Untersuchungen von Lawrence (1965). Durch Messung der Endolymph- und Mikrophonpotentiale konnte gezeigt werden, daß eine allgemeine Hypoxämie keinen Einfluß auf die Funktion der Sinneszellen hat. Erst die Sauerstoffverarmung in der Endolymphe führt zu einem Zusammenbruch der Mikrophonpotentiale.

Erstaunlicherweise wurde die Bedeutung der Innenohrflüssigkeiten für den ototoxischen Wirkungsmechanismus bis in die jüngste Zeit hinein kaum in Betracht gezogen und bei den Untersuchungen nie berücksichtigt. Ein wesentlicher Grund, warum man sich mit dem Innenohr und seinen Flüssigkeiten so wenig befaßt hat, ist sicher auch in dem sehr komplizierten Bau dieses Organes, das schon die alten Anatomen zu Recht mit dem Namen Labyrinth bedachten, sowie in der geringen Größe und außerordentlichen Empfindlichkeit der feinen Strukturen zu suchen, die für eine Untersuchung nur schwer zugänglich waren.

Die meisten klinischen und experimentellen Arbeiten, deren Zahl kaum noch zu übersehen ist, konzentrierten sich bisher in erster Linie auf die morphologischen und funktionellen Veränderungen an den Sinnesepithelien des Innenohres, dem Cortiorgan der Schnecke, den Cristae der Bogengänge und der Macula des Sacculus und Utriculus. Es handelt sich hier bei neben klinischen Beobachtungen fast ausschließlich um histologische, histochemische und elektrophysiologische Untersuchungen. In der folgenden Übersicht sind die bis heute vorliegenden Befunde und der Stand unserer Kenntnisse über die einzelnen Substanzen der Aminoglykosidgruppe und ihre ototoxischen Schädigungen kurz zusammengefaßt.

Fall ist in der praktischen Bedeutung dieser Antibiotika ist sicher auch die Hauptursache zu sehen, warum diese Substanzen bis zum heutigen Tage im Mittelpunkt ausgedehnter toxikologischer Untersuchungen stehen. Ziel dieser Bemühungen ist es, die toxische Wirkungsweise aufzudecken und durch Herabsetzung der Toxizität diese Antibiotikagruppe für einen größeren therapeutischen Anwendungsbereich nutzbar zu machen.

Die Aufmerksamkeit der Untersucher konzentrierte sich bisher überwiegend auf allgemeine toxikologische Mechanismen und mögliche chemische Reaktionen dieser Stoffe im Organismus. Zahlreiche Angriffspunkte werden beschrieben und diskutiert. Wir sind aber bis heute noch weit davon entfernt, von einer einheitlichen Auffassung sprechen zu können. Vor allem vermag keine der existierenden Theorien über die toxische Wirkung der Streptomycinantibiotika die „E“ wesentliche und grundlegende Frage zu erklären, warum ausschließlich das Innenohr und die Niere von der Cistiwirkung betroffen werden, während die anderen Organe verschont bleiben. Erstaunlicherweise fand dieses, für das Verständnis der Streptomycinintoxikation entscheidende Problem der Organspezifität wie auch Mieschek (1962) hervorhebt bisher nur wenig Beachtung. Aber gerade in diesem Phänomen so glauben wir ist die eigentliche Ursache für die Ototoxizität zu suchen. Die Beantwortung dieser Frage wird uns auch einer Erklärung der toxischen Wirkungsweise näherbringen.

Man muß sich zunächst fragen, besitzt das Innenohrlabyrinth besondere Merkmale, die eine bevorzugte Schädigung dieses Organes erklären? Wodurch unterscheidet sich das Innenohr von anderen Organen, vor allem von solchen, die eine ähnliche Struktur aufweisen wie z. B. die Sinnesapparate und das Nervensystem? Histologisch fallen an den Zellen des Innenohres bzw. des N. statoakusticus keinerlei Besonderheiten auf, die die Annahme einer spezifischen Sensibilität rechtfertigen würden. Auch in bio- bzw. histochemischer Hinsicht sind keine charakteristischen Unterschiede zu erkennen, die uns veranlassen könnten, eine besondere Affinität der toxischen Substanzen zu irgendwelchen chemischen Bausteinen oder Strukturen des Innenohres anzunehmen. Derartige Vorstellungen von einer „spezifischen Sensibilität“ oder „Affinität“, die immer wieder gerne zur Erklärung herangezogen werden, bleiben daher lediglich hypothetische Erwägung, für die es bis jetzt keinen Beweis gibt.

Auffällig ist jedoch der eigenartige anatomische Aufbau des Cochleovestibularapparates, der im Organismus nicht seinesgleichen hat und dem daher noch am ehesten für das Zustandekommen der spezifischen Ototoxikose eine Bedeutung zukommen scheint. Charakteristisch ist vor allem das zweikammerige Flüssigkeitssystem, die Peri- und Endolymphräume, die durch die Reißnersche Membran voneinander getrennt sind. Eine weitere Besonderheit des Innenohres ist darin zu sehen, daß die Sinneszellen in den Endolymphraum hineinragen und hier in unmittelbarem Kontakt mit der Lympheflüssigkeit stehen. Die Endolymph hat nicht nur die für den Hörvorgang wichtige mechanische Aufgabe, Schwingungen fort-

praktisch überhaupt nicht bei phylogenetisch höher entwickelten Lebewesen, wo es lediglich zu Gleichgewichtsstörungen kommen soll. Ignarski, McLeod und Graybiel (1966) gingen dieser Frage nach und untersuchten aus diesem Grunde die toxischen Streptomycinwirkungen auf das Hör- und Gleichgewichtsorgan an Totenkopfschnecken. Sie fanden hier jedoch die gleichen Veränderungen am Cortiorgan der Schnecke wie an den Cristae der Bogengänge, sodaß von einer selektiven Schädigung eines Organes nicht gesprochen werden kann. Auf Grund dieser Befunde warnen die Autoren dringend vor der allzu leichtfertigen Annahme, Streptomycin verursache bei höher entwickelten Lebewesen nur vestibuläre Störungen, aber keine Hörschäden.

Die Entwicklung des Dihydrostreptomycins (DSM) schien zunächst einen Fortschritt für die Streptomycintherapie darzustellen. DSM soll n. a. eine geringere akute Toxizität besitzen, nicht so häufig zu allergischen Reaktionen führen und außerdem stabiler sein als Streptomycin (SM). Bereits nach kurzer Zeit stellte sich aber heraus, daß DSM neben diesen sicher nicht zu unterschätzenden Vorzügen einen großen Nachteil aufweist. DSM ruft beim Menschen viel stärkere Hörschädigungen hervor als SM. Während Gleichgewichtsstörungen in der Regel im weiteren Verlauf durch zentrale Kompensationsvorgänge und auch mit Hilfe der optischen und taktilen Sinnesorgane wieder weitgehend kompensiert werden können, ist der Verlust des Gehörs für den Patienten viel schwerwiegender, da er irreversibel ist und durch kein anderes Organ ersetzt werden kann. Shambaugh *et al.* (1957) empfahlen daher auf die Anwendung des DSM zugunsten des SM zu verzichten, zumal beide Substanzen die gleiche antibiotische Wirksamkeit besitzen. Ähnliche Forderungen erhoben auch Harrison (1948) und Weinstein (1963). Die FDA (Food and Drug Administration) verlangt in ihrem Report vom 3.10.1960, daß DSM nur noch dann verwendet wird, wenn gegen Streptomycin eine Unverträglichkeit besteht. Die Verwendung von DSM in Penicillin-Streptomycin-Zubereitungen wurde für Amerika verboten. In der 17. Auflage der Pharmakopoe der Vereinigten Staaten von Amerika (USP Ausgabe 1965) wurde DSM nicht nur in Kombinationspräparaten, sondern sogar auch als Monoantibiotikum gestrichen. 1964 empfahl auch die Arzneimittelkommission der Deutschen Ärzteschaft DSM nur noch dann zu verordnen, wenn SM nicht vertragen wird. In einer erst kürzlich erschienenen Publikation empfiehlt P. Naumann (1968) DSM nicht mehr anzuwenden und auch SM nur noch bei bestimmten Indikationen, der Tuberkulose und Endokarditis, zu verordnen, sonst aber den antituberkulär wirksameren Antibiotika mit größerer therapeutischer Breite wie Ampicillin und Cephalosporin den Vorzug zu geben. Die Ablehnung des DSM ist nach Ansicht von Zorini (1966) und Mückter (1961 und 1966) nicht überzeugend begründet. Ihrer Meinung nach überwiegen, verglichen mit SM die Vorteile des DSM bei weitem seine Nachteile.

Die Feststellung, daß eine so gefürchtete Veränderung des Streptomycinmoleküls in Dihydrostreptomycin eine umgekehrte und entgegengesetzte

B BISHERIGE BEFUNDE UND HYPOTHESEN

I Klinische und experimentelle Befunde zur Ototoxizität der Aminoglykosidantibiotika

1 Streptomycin und Dihydrostreptomycin

Streptomycin (SM) wurde aus *Streptomyces griseus*-kulturen isoliert. Es ist nicht nur das älteste und therapeutisch wichtigste Antibiotikum dieser Gruppe sondern kann wohl auch als das am meisten untersuchte Antibiotikum überhaupt bezeichnet werden. Nach Mückler (1962) schädigt Streptomycin beim Menschen vor allem das Vestibularissystem (10-30 %) und nur in 2-3 % den cochleären Apparat. Da Streptomycin bevorzugt den Gleichgewichtsapparat zu schädigen scheint wurde es auch zur Ausschaltung des Vorhofbogenangangs-systems bei peripher bedingten Gleichgewichtsstörungen z. B. bei der Menière sehen Krankheit verwendet. Weder Fowler (1948) noch Hamberger *et al* (1949) Rüedi (1951) oder Hanson (1951) sahen bei dieser Behandlung wesentliche Hörstörungen. Andere Untersucher beobachteten allerdings stärkere Hörschäden und warnten deshalb vor der kritiklosen Anwendung des Streptomycins.

Die zahlreichen klinischen Befunde fanden in tierexperimentellen Untersuchungen ihre Bestätigung. Die Verhältnisse scheinen jedoch beim Tier von Spezies zu Spezies verschieden zu sein. Beim Meeresschweinchen und der Katze soll Streptomycin das Hörorgan sogar wesentlich stärker schädigen als den Bogengangssystem (Hawkins *et al.*, 1947; Tserberghlein 1962; Mückler 1962). Bei der Durchsicht der Literatur stößt man jedoch auf viele einander widersprechende Befunde. Mäsebeck (1961) z. B. stellte unter Streptomycin beim Meeresschweinchen genau das Gegenteil fest nämlich daß der Gleichgewichtsapparat stärker betroffen ist als die Cochlea. Hör- und Gleichgewichtsstörungen wurden bei der Katze außerdem von Keller *et al* (1955) bei Hunden von Mollter *et al* (1946, 1948 und 1950) ferner bei Kaninchen von Hawkins *et al* (1951) und bei Mäusen und Ratten von Causse *et al* (1948 und 1949) von Keller *et al* (1955) von Brigham und Nielsen (1958) sowie von Lagler *et al* (1960) und zahlreichen anderen Autoren beschrieben. Tauben zeigten einen vollständigen Verlust des Nachnystagmus, ohne daß dabei das Flugvermögen beeinträchtigt wurde. Dagegen konnten bei Hühnern unter Streptomycin erhebliche Gleichgewichtsstörungen mit ataktischen Erscheinungen beobachtet werden. Nach Weinauer *et al* (1957) reagieren auch Fische mit Selten- und Bauchlage.

Im allgemeinen wird angenommen daß Streptomycin Hörschädigungen ausschließlich bei niederen Tieren hervorruft, dagegen nur selten oder

praktisch überhaupt nicht bei phylogenetisch höher entwickelten Lebewesen, wo es lediglich zu Gleichgewichtsstörungen kommen soll. Igarashi, McLeod und Graybiel (1966) gingen dieser Frage nach und untersuchten aus diesem Grunde die toxischen Streptomycinwirkungen auf das Hör- und Gleichgewichtsorgan an Totenkopffischen. Sie fanden hier jedoch die gleichen Veränderungen am Cortiorgan der Schnecke wie an den Cristae der Bogengänge, sodaß von einer selektiven Schädigung eines Organes nicht gesprochen werden kann. Auf Grund dieser Befunde warnen die Autoren dringend vor der allzu leichtfertigen Annahme, Streptomycin verursache bei höher entwickelten Lebewesen nur vestibuläre Störungen, aber keine Hörschäden.

Die Entwicklung des Dihydrostreptomycins (DSM) schien zunächst einen Fortschritt für die Streptomycintherapie darzustellen. DSM soll n. a. eine geringere akute Toxizität besitzen, nicht so häufig zu allergischen Reaktionen führen und außerdem stabiler sein als Streptomycin (SM). Bereits nach kurzer Zeit stellte sich aber heraus, daß DSM neben diesen scheinbar nicht zu unterschätzenden Vorzügen einen großen Nachteil aufweist. DSM ruft beim Menschen viel stärkere Hörschädigungen hervor als SM. Während Gleichgewichtsstörungen in der Regel im weiteren Verlauf durch zentrale Kompensationsvorgänge und auch mit Hilfe der optischen und taktilen Sinnesorgane wieder weitgehend kompensiert werden können, ist der Verlust des Gehörs für den Patienten viel schwerwiegender, da er irreversibel ist und durch kein anderes Organ ersetzt werden kann. Shambaugh et al. (1959) empfahlen daher auf die Anwendung des DSM zugunsten des SM zu verzichten, zumal beide Substanzen die gleiche antibiotische Wirksamkeit besitzen. Ähnliche Forderungen erhoben auch Harrison (1940) und Weinstein (1962). Die FDA (Food and Drug Administration) verlangt in ihrem Report vom 3. 10. 1960, daß DSM nur noch dann verwendet wird, wenn gegen Streptomycin eine Unverträglichkeit besteht. Die Verwendung von DSM in Penicillin-Streptomycin-Zubereitungen wurde für Amerika verboten. In der 17. Auflage der Pharmakopoe der Vereinigten Staaten von Amerika (USP Ausgabe 1963) wurde DSM nicht nur in Kombinationspräparaten, sondern sogar auch als Monantibiotikum gestrichen. 1964 empfahl auch die Arzneimittelkommission der Deutschen Ärzteschaft, DSM nur noch dann zu verordnen, wenn SM nicht vertragen wird. In einer erst kürzlich erschienenen Publikation empfiehlt P. Naumann (1966) DSM nicht mehr anzuwenden und auch SM nur noch bei bestimmten Indikationen, der Tuberkulose und Endokarditis, zu verordnen, sonst aber den antibakteriell wirksameren Antibiotika mit größerer therapeutischer Breite wie Ampicillin und Cephalosporin den Vorzug zu geben. Die Ablehnung des DSM ist nach Ansicht von Zorini (1966) und Mückter (1961 und 1966) nicht überzeugend begründet. Ihrer Meinung nach überwiegen verglichen mit SM, die Vorteile des DSM bei weitem seine Nachteile.

Die Feststellung, daß eine so geringfügige Veränderung des Streptomycinmoleküls in Dihydrostreptomycin eine umgekehrte und entgegengesetzte

toxische Wirkung haben soll stellt ein interessantes Phänomen dar wofür es bis heute keine Erklärung gibt. Es gilt zwar allgemein die Regel daß SM Gleichgewichtsstörungen und DSM Hörschädigungen verursacht. Dieses gegensätzliche Verhalten von SM und DSM sollte aber wie eben schon am Beispiel des SM gezeigt wurde nicht überbewertet werden. Wenn man die in der Literatur mitgeteilten widerspruchsvollen Befunde berücksichtigt erscheint eine vorsichtiger Beurteilung angeraten. Besser wäre es zumindest da meistens früher oder später bei beiden Substanzen sowohl cochleale als auch vestibuläre Störungen auftreten von einer bevorzugten Schädigung des Vestibularapparates oder des Cortiorganes zu sprechen.

Durch Reinigung der Streptomycinpräparate insbesondere von Lösungsrückständen (Methylalkohol) und Metallionen (Calcium) konnten die toxischen Nebenwirkungen erheblich vermindert werden. Kimmmerle und Gösswald (1956) sowie Kuschinski, Löffmann und Pracht (1960) vermochten bei Ratten selbst nach wochenlanger Behandlung keine SM- und DSM-Schädigungen nachzuweisen. Kimmmerle und Gösswald gingen sogar soweit alle bisherigen Befunde und Mitteilungen über toxische Hörsstörungen nach Dihydrostreptomycin nicht nur bei der Ratte sondern auch bei anderen Tieren und sogar beim Menschen in Frage zu stellen. Im Gegensatz hierzu berichten aber zahlreiche andere Untersucher wie Courvoisier und Leau (1956), Ducrot, Leau und Cosar (1956), Osterberg *et al.* (1956), Becari, Cuida und Molinengo (1957), Maeda *et al.* (1957), Takeuchi *et al.* (1958) sowie Tisch, Huftalen und Dickson 1958 über deutliche Hörschäden bei Ratten nach DSM.

Besonders aufschlußreich sind angesichts dieser widersprechenden Befunde die von Mahady und Mitarbeitern in den Jahren 1953 und 1956 unter gleichen Bedingungen durchgeführten vergleichenden Untersuchungen mit alten handelsüblichen DSM-Präparaten und hochgereinigtem kristallinem DSM-Sulfat. Die beiden Präparate unterschieden sich hierbei nicht in ihren ototoxischen Eigenschaften. Es muß daher in Übereinstimmung mit Mückler angenommen werden, daß die spezifisch ototoxische Wirkung nicht auf Verunreinigungen zurückzuführen ist sondern wie Molitor bereits im Jahre 1948 vermutete wahrscheinlich ausschließlich auf dem SM-Molekül und seinen Abbauprodukten beruht. Durch die Reinigung des Streptomycins gelang es allerdings, darin stimmen alle Untersucher überein die allergischen Nebenwirkungen, die zu den häufigsten Komplikationen der Streptomycintherapie zählten praktisch vollständig zu beseitigen.

Widersprechende Angaben finden sich auch hinsichtlich der Lokalisation der Streptomycinschädigungen. Die von Winston, Lewy, Laranteau, Marden und Cramer (1948) festgestellten Veränderungen an den Purkinjezellen am Flocculus und Nodus, am Deiterschen Kern und Nucleus dentatus des Kleinhirns sowie im medialen Vestibulariskern sprechen für einen zentralen Angriffspunkt des SM. Die Ursache hierfür glauben die Untersucher in einer erhöhten Permeabilität der Hirnschranke sehen zu

können. Winslow und Mitarbeiter konnten zeigen, daß die Bluthirn schranke unter SM für Trypanblau durchlässig wird. Für die Annahme eines zentralen Angriffspunktes würden auch die Befunde von Floberg, Hamberger und Hyden (1949) sprechen, die unter SM eine Abnahme des Nucleinsäuregehaltes in den Zellen des Ganglion vestibulare des Meeresschweinchens beobachteten. Escher (1949) berichtete außerdem über Ganglienzelluntergänge im Ganglion triangulare und Nucleus angularis. Secondi (1954) sah auch Schädigungen an den Vestibulariskernen, den Purkinjezellen und im Hippocampus. Christensen, Hertz, Riskaer und Vraa Jensen (1950) unterzogen nicht nur die zentralen Bahnen des N. statoakusticus, sondern auch den peripheren Sinnesapparat einer histologischen Untersuchung. Sie fanden eine Degeneration der rhombencephalen Cochlearis- und Vestibulariskerne, des Ganglion vestibulare sowie der Purkinjezellen des Kleinhirns. Die Sinnesepithelien des Cortiorgans und des Vestibularapparates schienen dagegen intakt zu sein. Bei Untersuchungen, die einige Jahre später von der gleichen Forschergruppe (Riskaer Christensen, Petersen und Weidman, 1956) durchgeführt wurden, stellte man jedoch auch periphere Schädigungen am Labyrinth fest, die aber nur gering sein sollen gegenüber den Veränderungen am ZNS.

Im Gegensatz zu den oben aufgeführten Untersuchungsergebnissen kam Greven (1933) auf Grund histologischer Untersuchungen zu dem Schluß, daß SM auf die zentralen Bahnen und Umschaltstellen des N. Statoakusticus keinen Einfluß hat. Auch Causé (1949) beobachtete bei Mäusen nur periphere Schädigungen an den Cristae ampullares, den Maculae staticae und am Cortiorgan, während die cochleovestibulären Kerngebiete keine Zeichen einer Schädigung aufwiesen. Eine toxische Wirkung des Streptomycins auf die peripheren Sinneszellen wurde ferner von Graf (1951) Berg (1951) Rüedi, Furrer Luthy Nager und Tschirren (1952) Hawkins, Wolcott und O'Shanny (1956-1957) Catalano und Madonna (1956) Neumann und Neubert (1958) und vielen anderen und in jüngster Zeit noch von Holde Hals und Hando (1966) sowie Igarashi, McLeod und Graybiel (1966) beschrieben.

Müsebeck und Schätzle (1963) und Müsebeck (1963, 1964) sahen allerdings die ersten Zeichen einer Schädigung nicht an den Sinneszellen, sondern vielmehr an den Mitochondrien der sog. sekretorischen Epithelien des Innenohres. Die Veränderungen an den Mitochondrien der Sinneszellen treten, wie sich histochemisch nachweisen ließ, erst später auf und sollen sekundärer Natur sein.

Bei diesem kurzen Überblick fällt auf, daß sich Mitteilungen über toxische Streptomycinwirkungen auf das ZNS vor allem in der älteren Literatur finden. Die weitaus überwiegende Zahl der Berichte, insbesondere aus der jüngsten Zeit, spricht für eine primär periphere Schädigung.

Eckel und Altenburger (1960) vermuten die Ursache für die verschiedenen Befunde in den unterschiedlichen Dosierungen. Sie glauben, daß in einem mittleren Dosierungsbereich ausschließlich periphere Schädigungen auf

treten und nur durch sehr hohe bereits zu einer Allgemeintoxikation führende Streptomycinmengen Veränderungen im Kerngebiet hervorgerufen werden. Diese Auffassung wird heute allgemein vertreten. Dennoch machten Neumann und Neubert (1958) auf das Mißverhältnis zwischen den peripheren morphologischen Befunden und den ausgeprägten funktionellen Ausfallerscheinungen aufmerksam. Sie nehmen aus diesem Grunde an, daß für die Hör- und Gleichgewichtsstörungen neben peripheren auch zentralnervöse SM-Schädigungen verantwortlich gemacht werden müssen. Die Frage bleibt jedoch unbeantwortet, ob die zentralen Veränderungen ebenfalls primärer Natur oder möglicherweise nur sekundär bedingt sind. Engström und auch Holonen (1965) äußerten die Vermutung, daß es sich bei den Veränderungen im Nervensystem um sekundäre Degenerationserscheinungen der zugeordneten Nervenbahnen handelt. Eine langsam fortschreitende Degeneration würde auch den meist erst sehr spät auftretenden und oft nach Absetzen der Therapie noch über eine lange Zeit langsam fortschreitenden Funktionsausfall erklären. Zeitlich gesehen treten in der Regel die ersten Zeichen einer Gleichgewichtsstörung wenige Wochen nach Behandlungsbeginn in Erscheinung, während sich eine Schwerhörigkeit häufig sehr viel später, oft erst nach einer Latenzzeit von wenigen Tagen bis zu 6 oder sogar 7 Monaten nach Absetzen der Therapie bemerkbar macht (Shambaugh *et al.* 1959; Harrison, 1959-60; Rossi *et al.* 1961; Mäckler 1961).

Diese Übersicht zeigt, wie widerspruchsvoll die Befunde allein schon im Vergleich der toxischen Wirkungen des Streptomycins und des Dihydrostreptomycins sind. Es liegen außerdem widersprechende Ergebnisse bei den einzelnen Tierespezies vor. Ferner bestehen unterschiedliche Auffassungen darüber, ob der toxische Wirkungsort im peripheren Sinnesorgan oder im ZNS zu suchen ist. Selbst über die Schädigungen im Innenohr gehen die Meinungen auseinander. Die abweichenden Befunde der Untersucher lassen sich nur zum Teil durch die verschiedenartigen Versuchsbedingungen und Untersuchungsmethoden erklären. Neumann und Neubert (1958) wiesen schon auf die großen individuellen Schwankungen der unter Streptomycin auftretenden Störungen hin. Die Grenze der morphologisch sichtbaren Veränderungen variiert nach ihren Angaben beim Meerschweinchen zwischen einer Dosis von 2 und 8 g DSM/kg. Ein weiterer Grund für die großen Differenzen in den Untersuchungsergebnissen ist möglicherweise auch in der relativ schwachen Ototoxizität des Streptomycins zu suchen. Jedenfalls ist es auffällig, daß über die wesentlich stärker toxischen Substanzen wie Neomycin und Kanamycin im Gegensatz zum Streptomycin viel einheitlichere Ergebnisse und weitgehend übereinstimmende Auffassungen vorliegen.

• Neomycin

Die schnelle Resistenzbildung der Tuberkelbazillen gegen Streptomycin veranlaßte Waksman und Lechevallier nach weiteren Antibiotika zu suchen.

Dieser Weg führte schließlich im Jahre 1949 zur Isolierung des Neomycins aus *Streptomyces fradiae*. Neomycin besteht aus 3 basischen nahe verwandten Antibiotika, von denen eines das Neomycin A ist. Neomycin hat überwiegend eine bakterizide Wirkung und zeichnet sich durch ein besonders breites antibiotisches Spektrum aus. Es ist wirksam gegen gramnegative Keime einschließlich *Pseudomonas aeruginosa* (pyocyanus) gegen alle Staphylokokken und hat außerdem auch einen tuberkulostatischen Effekt.

Die 1 klinischen Beobachtungen über Hörschäden durch Neomycin stammen von Carr und Mitarbeitern (1950, 1951) sowie von Walsbren und Spink (1950). Walsbren und Spink fiel aber schon auf, daß bei allen Patienten, die unter der Neomycin-Behandlung einen Hörverlust erlitten, stets irgendeine Nierenkrankung vorlag. Es folgten zahlreiche weitere klinische Mitteilungen von Goldner (1958), Körte-Stöppler und Mittag (1958), Greenwood (1959) und Leach (1962), die vor allem über Hörschädigungen berichten. Die Hörstörungen sollen oft erst Tage ja sogar Wochen nach einer Behandlung auftreten und zuerst die hohen Frequenzen betreffen. Dagegen fanden sich vestibuläre Schädigungen unter Neomycin nur in einzelnen Fällen und auch hier nur in geringem Ausmaß.

Lindsay und Mitarbeiter konnten die Felsenbeine eines an Endocarditis verstorbenen Patienten untersuchen, der mit 16 g Neomycin behandelt worden war und dabei erstarbte. Sie fanden ebenfalls keine Veränderungen des vestibulären Sinnesepithels. Auch im Bereich der *Stria vascularis* waren keine Schädigungen zu erkennen, dagegen zeigten sich ausgedehnte Zerstörungen bzw. ein vollständiges Verschwinden der Haarzellen, insbesondere der inneren Zellen.

Tierexperimentell konnten erstmals Rüdel, Graf und Tschirren (1953) mit Neomycin beim Meerschweinchen cochleotoxische Schädigungen erzeugen und histologisch untersuchen. Die Schädigungen betrafen entsprechend dem besonders ausgeprägten Hörverlust in den hohen Frequenzen vor allem die Haarzellen der basalen Windungen, und zwar im Gegensatz zu Lindsay vor allem die äußeren Zellen. Die den einzelnen Abschnitten des Cortiorgans zugeordneten neuronalen Elemente wiesen ebenfalls eine entsprechende Verminderung der Anzahl ihrer Nervenfasern und Ganglienzellen erkennen. Rüdel und Mitarbeitern kommt außerdem das Verdict zu, als erste festzustellen zu haben, daß die Veränderungen nicht nur auf die Sinneszellen beschränkt sind, sondern auch die *Stria vascularis* betreffen.

Ein Vergleich der ototoxischen Wirkungen der einzelnen basischen Streptomyces-Antibiotika zeigte, daß Neomycin die weitaus stärksten ototoxischen Schädigungen hervorruft (Hawkins, 1952; Hawkins und Lurie, 1953; Courvoisier und Leau, 1956). Tybergheim (1962) untersuchte auch die verschiedenen Salze des Neomycins, die Pantothenatkomplexe und die Sulf-Verbindung. An der Abnahme der Mikrophonpotentiale stellte er fest, daß Neomycin die schwersten Haarzellenschädigungen von allen Streptomyces-Antibiotika verursacht. Die Toxizität des Neomycins konnte auch

treten und nur durch sehr hohe bereits zu einer Allgemeintoxikation führende Streptomycinmengen Veränderungen im Kerngebiet hervorgerufen werden. Diese Auffassung wird heute allgemein vertreten. Dennoch machten Neumann und Neubert (1958) auf das Mißverhältnis zwischen den peripheren morphologischen Befunden und den ausgeprägten funktionellen Ausfallserscheinungen aufmerksam. Sie nehmen aus diesem Grunde an, daß für die Hör- und Gleichgewichtstörungen neben peripheren auch zentralnervöse SM-Schädigungen verantwortlich gemacht werden müssen. Die Frage bleibt jedoch unbeantwortet, ob die zentralen Veränderungen ebenfalls primärer Natur oder möglicherweise nur sekundär bedingt sind. Engström und auch Kohonen (1965) äußerten die Vermutung, daß es sich bei den Veränderungen im Nervensystem um sekundäre Degenerationserscheinungen der zugeordneten Nervenbahnen handelt. Eine langsam fortschreitende Degeneration würde auch den meist erst sehr spät auftretenden und oft nach Absetzen der Therapie noch über eine lange Zeit langsam fortschreitenden Funktionsausfall erklären. Zeitlich gesehen treten in der Regel die ersten Zeichen einer Gleichgewichtsstörung wenige Wochen nach Behandlungsbeginn in Erscheinung, während sich eine Schwerhörigkeit häufig sehr viel später, oft erst nach einer Latenzzeit von wenigen Tagen bis zu 6 oder sogar 7 Monaten nach Absetzen der Therapie bemerkbar macht (Shambaugh *et al.*, 1959; Harrison, 1959-60; Rossi *et al.* 1961; Mückter 1961).

Diese Übersicht zeigt, wie widerspruchsvoll die Befunde allein schon im Vergleich der toxischen Wirkungen des Streptomycins und des Dihydrostreptomycins sind. Es liegen außerdem widersprechende Ergebnisse bei den einzelnen Tierarten vor. Ferner bestehen unterschiedliche Auffassungen darüber, ob der toxische Wirkungsort im peripheren Sinnesorgan oder im ZNS zu suchen ist. Selbst über die Schädigungen im Innenohr gehen die Meinungen auseinander. Die abweichenden Befunde der Untersucher lassen sich nur zum Teil durch die verschiedenartigen Versuchsbedingungen und Untersuchungsmethoden erklären. Neumann und Neubert (1958) wiesen schon auf die großen individuellen Schwankungen der unter Streptomycin auftretenden Störungen hin. Die Creuze der morphologisch sichtbaren Veränderungen variiert nach ihren Angaben beim Meeresschweinchen zwischen einer Dosis von 2 und 8 g DSM/kg. Ein weiterer Grund für die großen Differenzen in den Untersuchungsergebnissen ist möglicherweise auch in der relativ schwachen Ototoxizität des Streptomycins zu suchen. Jedenfalls ist es auffällig, daß über die wesentlich stärker toxischen Substanzen wie Neomycin und Kanamycin im Gegensatz zum Streptomycin viel einheitlichere Ergebnisse und weitgehend übereinstimmende Auffassungen vorliegen.

2. Neomycin

Die schnelle Resistenzbildung der Tuberkelbazillen gegen Streptomycin veranlaßte Waksman und Lechevalier nach weiteren Antibiotika zu suchen.

Dieser Weg führte schließlich im Jahre 1949 zur Isolierung des Neomycins aus *Streptomyces fradiae*. Neomycin besteht aus 3 basischen nahe verwandten Antibiotika, von denen eines das Neomycin A ist. Neomycin hat überwiegend eine bakterizide Wirkung und zeichnet sich durch ein besonders breites antibakterielles Spektrum aus. Es ist wirksam gegen gramnegative Keime einschließlich *Pseudomonas aeruginosa* (pyocyaneus) gegen alle Staphylokokken und hat außerdem auch einen tuberkulostatischen Effekt.

Die 1 klinischen Beobachtungen über Hörschäden durch Neomycin stammen von Carr und Mitarbeitern (1950 1951) sowie von Walsbren und Spink (1950) Walsbren und Spink fiel aber schon auf, daß bei allen Patienten, die unter der Neomycin-Behandlung einen Hörverlust erlitten, stets irgendeine Nierenkrankung vorlag. Es folgten zahlreiche weitere klinische Mitteilungen von Goldner (1958) Hörige-Stöppler und Mitting (1958) Greenwood (1959) und Leach (1962) die vor allem über Hörschädigungen berichten. Die Hörstörungen sollen oft erst Tage, ja sogar Wochen nach einer Behandlung auftreten und zuerst die hohen Frequenzen betreffen. Dagegen fanden sich vestibuläre Schädigungen unter Neomycin nur in einzelnen Fällen und auch hier nur in geringem Ausmaß.

Lindsay und Mitarbeiter konnten die Felsenbeine eines an Endocarditis verstorbenen Patienten untersuchen, der mit 16 g Neomycin behandelt worden war und dabei erstarb. Sie fanden ebenfalls keine Veränderungen des vestibulären Sinnesepithels. Auch im Bereich der Stria vascularis waren keine Schädigungen zu erkennen, dagegen zeigten sich ausgedehnte Zerstörungen bzw. ein vollständiges Verschwinden der Haarzellen, insbesondere der inneren Zellen.

Tierexperimentell konnten erstmals Rüedi, Graf und Tschirren (1953) mit Neomycin beim Meeresschweinchen cochleotoxische Schädigungen erzeugen und histologisch untersuchen. Die Schädigungen betrafen entsprechend dem besonders ausgeprägten Hörverlust in den hohen Frequenzen vor allem die Haarzellen der basalen Windungen, und zwar im Gegensatz zu Lindsay vor allem die äußeren Zellen. Die den einzelnen Abschnitten des Cortiorgans zugeordneten neuronalen Elemente ließen ebenfalls eine entsprechende Verminderung der Anzahl ihrer Nervenfasern und Ganglienzellen erkennen. Rüedi und Mitarbeitern kommt außerdem das Verdienst zu, als erste festgestellt zu haben, daß die Veränderungen nicht nur auf die Sinneszellen beschränkt sind, sondern auch die Stria vascularis betreffen.

Ein Vergleich der ototoxischen Wirkungen der einzelnen basischen *Streptomyces*-Antibiotika zeigte, daß Neomycin die weitaus stärksten ototoxischen Schädigungen hervorruft (Hawkins, 1952; Hawkins und Lurie 1953; Courrier und Leau, 1956). Tybergheim (1962) untersuchte auch die verschiedenen Salze des Neomycins, die Pantothensäurekomplexe und die Sulfatverbindung. An der Abnahme der Mikrophonopotentiale stellte er fest, daß Neomycin die schwersten Haarzellenschädigungen von allen *Streptomyces*-Antibiotika verursacht. Die Toxizität des Neomycins konnte auch

durch Zusatz von Panthenol nicht herabgesetzt werden. Die besonders ausgeprägte Ototoxizität des Neomycins hebt auch Finland (1961) in seiner Monographie hervor.

Zu dem gleichen Ergebnis kamen Riskær und Mitarbeiter (1956) die den toxischen Einfluß des Neomycins auf die Haarzellen, die Stria vascularis und die neuralen Elemente mit Streptomycin, Viomycin und Polymyxin B verglichen. Neomycin erwies sich hierbei am stärksten toxisch. Sie konnten ebenfalls unter Neomycin keine Schädigungen am Vestibularapparat feststellen.

Friedmann und Bird (1961) führten ihre Untersuchungen an der Otolyste von Hühnerembryonen durch und kamen hier zu der gleichen Feststellung. Neomycin und Kanamycin weisen zwar im Prinzip ein ähnliches Schädigungsbild auf, die Veränderungen unter Neomycin waren aber viel ausgeprägter als bei Kanamycin.

3 Kanamycin

Kanamycin wurde 1957 von Umezawa aus dem Filtrat einer Kultur von *Streptomyces strain*, der Umezawa den Namen *Streptomyces kanamyceticus* gab, isoliert. Sowohl in chemischer Hinsicht als auch in seinem antibiotischen Wirkungsspektrum gleicht Kanamycin dem Neomycin.

Es überraschte daher nicht weiter, als bald eine große Zahl wissenschaftlicher Arbeiten über die nephro- und ototoxischen Wirkungen des Kanamycins erschien (Bunn *et al.* 1958, White, 1958, Ichikawa, 1959, Donomae 1958, Finegold *et al.* 1958, March 1959, Frost *et al.*, 1958/59 und 1960, Naunton and Ward, 1959, Lustberg und Hamburger 1959, Lecca *et al.*, 1959, Bouche *et al.* 1960, Alfthan *et al.*, 1962, Haapanen, 1963, Degreaf 1964, Marcellan, 1965).

Ähnlich wie bei Neomycin stehen auch bei Kanamycin Hörschädigungen im Vordergrund, die zuerst die hohen Frequenzen betreffen. Vestibuläre Störungen wurden dagegen nur in seltenen Fällen beschrieben, so z. B. von Matz (1965). Besonders schwere Ototoxikosen beobachtete man bei Nierenschädigungen verschiedener Genese (Ichikawa, 1958, White 1958, Naunton und Ward 1959, Lecca, Terry, Maggiolo und Morales, 1959).

Im Tierexperiment konnten mit Hilfe elektrophysiologischer Methoden Hörschädigungen von Hawkins (1959), Tyberghien (1962), Owada (1962) sowie Plattig und Keldel (1965) nachgewiesen werden. Hawkins unterzog die Tiere außerdem einer histologischen Untersuchung. Er fand bei halben Meerschweinchen und weniger ausgeprägt bei Ratten, Schädigungen der äußeren Haarzellen, vor allem in den basalen Windungen, während die inneren Haarzellen in allen Windungen fehlten. Es war aber auch eine Verringerung der Ganglienzellen und Nervenfasern in der Lamina spiralis ossea feststellbar. Dagegen erwiesen sich das Ganglion spirale und Neuroepithel der Cristae ampullares beim Meerschweinchen als normal.

Einen Verlust an Ganglienzellen und Haarzellenschädigungen in den un-

teren Windungen der Meeresschnecken Cochlea beschrieben ebenfalls Catalano und Altarbeiter (1961)

Ähnliche histologische Befunde erhoben Ward und Fernandez (1961) Darüber hinaus stellten sie aber auch Veränderungen im Kleinhirn und Hirnstamm, sowie eine Verminderung nicht nur der Ganglienzellen, sondern auch der Fasern des Hörnerven fest

Mesnilles und Costa kamen 1962 im wesentlichen zu dem gleichen Ergebnis. Sie heben jedoch hervor daß die Schädigungen im Bereich des ZNS und des Ganglions nur gering waren, verglichen mit den ausgeprägten Veränderungen am peripheren Sinnesapparat. Im Gegensatz zu Hawkins sahen sie auch Schädigungen an den Sinneszellen des Gleichgewichtsapparates.

Darrowitz und de Lima Sobrinho (1962) fielen neben Zerstörungen der äußeren Haarzellen in den Basalwindungen außerdem leichte Veränderungen an den Stützzellen auf. Reddy und Igarashi (1962) sind sogar der Meinung, daß die Stützzellen besonders empfindlich sind und als erste geschädigt werden, während die Haarzellschädigungen später nachfolgen sollten.

Mit Hilfe der Händchenpräparation nach Neubert (1856) untersuchten Beck und Krahl (1962) die Kanamycinschädigungen an der Meeresschnecken Cochlea. Sie stellten zunächst als 1. Zeichen einer toxischen Störung eine Unregelmäßigkeit an den Kernen der äußeren Haarzellen und zwar in der 1. innersten Reihe der unteren Schneckenwindungen fest, die später auf die 2. und 3. Reihe der äußeren Haarzellen übergreift. Auch Müsebeck sah regelmäßig, daß die 1. Reihe der äußeren Haarzellen am empfindlichsten geschädigt wurde, die Störungen in der 2. und 3. Reihe dagegen deutlich geringer waren, während die inneren Haarzellen relativ widerstandsfähig erschienen.

Neben den Sinnesepithelschädigungen ruft Kanamycin nach den Untersuchungen von Beck und Krahl auch an den Epithelzellen der Stria vascularis und den Deiterschen Zellen ähnliche Veränderungen hervor wie sie schon unter Streptomycin (Müsebeck und Schäfer) und Neomycin (Müedl) beschrieben wurden. Die stärksten Schäden fanden auch als bemerkenswerterweise in der oberflächlichsten, dem Endolymphraum zugewandten Epithelschicht. Darüber hinaus fanden Beck und Krahl auch zentrale Veränderungen an den Ganglienzellen, vor allem im Kerngebiet. Das Ausmaß der Schädigung nimmt, wie sich histochemisch zeigen ließ, vom peripheren Sinnesapparat über die Kerngebiete hin zu den übergeordneten Hirnabschnitten deutlich ab.

Ardouin, Sait und Johari (1963) beobachteten fast ausschließlich eine Schädigung der äußeren Haarzellen, insbesondere der unteren Windungen. Dagegen zeigten sich die inneren Haarzellen, die Stützzellen und neuronalen Elemente bei ihren Untersuchungen unauffällig dar

Neue Erkenntnisse brachten die kombinierten Licht und elektronenmikroskopischen Untersuchungen Farkashidya, Blacka und Briants (1963) Be-

sonders bemerkenswert ist im Rahmen unserer Betrachtungen der Schluß, den Farkashildt und seine Mitarbeiter aus ihren Untersuchungen ziehen. Es fiel ihnen auf, daß die ersten Degenerationszeichen mit Verklumpungen der Mitochondrien und des endoplasmatischen Retikulums stets im supranukleären dem Endolymphraum zugekehrten Bereich der Zelle auftraten. Sie äußern daher den Verdacht, daß die Kanamycinschädigung vom Endolymphraum aus erfolgt, wo eine besonders hohe Konzentration des Antibiotikums vermutet wird.

Die gleichen, im Tierexperiment beobachteten Veränderungen im Bereich der basalen Windungen wurden auch in den 3 bis heute untersuchten Fällen beim Menschen beschrieben (Benitez, Schuknecht und Brandenburg, 1962; Jorgensen und Schmidt 1962; Matz, Wallace und Ward (1963)) hatten die Gelegenheit, ein menschliches Felsenbein nach einer kurzfristigen Kanamycinbehandlung, die zu einer Taubheit und einem Ausfall der kalorischen Erregbarkeit der Bogengangapparate geführt hatte, histologisch zu untersuchen. Ein Vergleich mit experimentell erzeugten Kanamycinschädigungen am Innenohr des Meerschweinchens führte die Untersucher zu der Feststellung, daß kein Unterschied zwischen der Histopathologie der menschlichen Ototoxikose und der tierexperimentellen Innenohrintoxikation besteht. Erstaunlicherweise fanden die Untersucher trotz des klinisch eindeutigen Ausfalls der Vorhofbogengangsfunktion keine morphologisch fassbaren Veränderungen an den peripheren Vestibularapparaten. Sie vermuten daher die Ursache für die Gleichgewichtsregulationsstörung in den übergeordneten Zentren des ZNS.

4. *Viomycin, Framycetin, Paromomycin und Gentamicin*

Zur Gruppe der Aminoglykosidantibiotika zählen außer Streptomycin, Neomycin und Kanamycin noch Viomycin, Framycetin, das Vancomycin und Paromomycin auch Aminosidine (Gabromycin?) genannt sowie das Gentamicin. Sie sollen hier nur der Vollständigkeit halber kurz erwähnt werden. Über ihre Pharmakologie und Toxikologie ist bis heute nur wenig bekannt.

Viomycin aus *Streptomyces puniceus*, das vor allem zur Behandlung der Tuberkulose Anwendung findet, ruft ebenfalls, wie Werner und Mitarbeiter 1961 erstmals berichteten, Innenohrschädigungen und zwar in 1 Linie Gleichgewichtsstörungen hervor. Weniger ausgeprägt sind bei Viomycin die Hörschädigungen. Es folgten noch weitere klinische Mitteilungen über die Toxizität des Viomycins von Schaffeld *et al.* (1961), Litt *et al.* (1962), Tucker *et al.* (1964) sowie Edge *et al.* (1966). Nach Daly und Cohen ist Viomycin gegen Tuberkelbazillen nur 1/3 so wirksam wie Streptomycin, dafür aber deutlich toxischer als dieses. Die Toxizität soll jedoch nicht ganz so ausgeprägt sein wie bei Kanamycin.

Über *Framycetin*, das aus *Streptomyces lavendulae* gewonnen wird, liegen bisher nur wenige Untersuchungsergebnisse vor. Massenaud und Dérœche

(1934) haben bei ihren Patienten starke toxische Nebenwirkungen auf Ohren und Nieren.

Tierexperimentell gelang es erstmals Kohonen (1965) Schädigungen der äußeren Haarzellen durch Framycelin nachzuweisen. Hinsichtlich seiner Ototoxizität scheint es dem Neomycin nur wenig nachzustehen.

Über das Antibiotikum *Aminosidin*, das chemisch mit Paromomycin identisch ist und von Canavari und Scott (1939) aus *Streptomyces chrysomycetinus* isoliert wurde, berichtete erst kürzlich Marsellan (1965). Ein Vergleich mit Kanamycin ergab, daß Aminosidin sowohl gemessen am Gewichtsabfall der Versuchstiere als auch hinsichtlich seiner Hörschädigungen den Wirkung etwas toxischer ist als Kanamycin.

An der Ratte und Katze (Arcamone et al. 1959) und am Meeresschweinchen (Manzo und Nee, 1961) konnten sowohl cochleo- als auch vestibulotoxische Effekte des Aminosidins nachgewiesen werden. Während beim Meeresschweinchen die Hörschädigungen im Vordergrund standen, zeigten Katzen vor allem vestibuläre Symptome.

Gentamycin (Befobactin[®]) wurde erst 1963 von der Arbeitsgruppe M. J. Weinstein aus den Fermentationsansätzen bis dahin noch unbekannter *Streptomyces*-arten, *Micromonospora purpurea* und *M. echinospora*, gewonnen. Nach Wersäll und Lundquist weist es die weitaus stärksten vestibulo- und cochleotoxischen Erscheinungen von allen Aminoglykosidantibiotika auf, besitzt aber andererseits besonders hervorragende antibakterielle Eigenschaften, z. B. gegen therapieresistente *Staphylokokken*, *Pseudomonas aeruginosa* und andere Problemkeime. Seine starke Ototoxizität wird durch eine 10fach höhere antibakterielle Wirksamkeit mehr als aufgewogen, sodaß nur 1/10 der sonst üblichen Dosen verabreicht werden muß. Holz und Soda (1967) verglichen antibiologisch gleichwertige Dosen von Streptomycin, Neomycin und Gentamycin. Sie stellten fest, daß Gentamycin in dieser Dosierung sogar weniger toxisch ist als Streptomycin.

Zusammenfassend läßt sich von den Antibiotika der Aminoglykosidgruppe folgendes sagen:

Die typischen Schädigungen weisen bei allen Substanzen die gleichen Grundzüge auf. Übereinstimmend mit Mäsebeck, Kohonen und vielen anderen kann als wahrscheinlich angenommen werden, daß der primäre Schädigungsort der bakteriellen Streptomycesantibiotika im peripheren Sinnesorgan zu suchen ist. Den Beweis hierfür lieferten schon die frühen Untersuchungen von Cause und Berg und erst recht die mit verbesserten Methoden durchgeführten Untersuchungen der letzten Jahre.

Die Schädigung der einzelnen Abschnitte und Zellen des Innenohres erfolgt in einer bestimmten gesetzmäßigen Reihenfolge. Dieses sog. Schädigungsmuster scheint ebenfalls bei allen Antibiotika das gleiche zu sein.

Beck und Kralik (1962) nahmen zunächst an, daß die bevorzugte Schädigung der basalen Haarzellen auf einer langsameren Strömungsgeschwindigkeit des Blutes in den unteren Schneckenwindungen beruht. Diese Vorstellung widerlegte Kohonen (1962), indem er zeigte, daß z. B. die inneren

Haarzellen im Gegensatz zu den äußeren Zellen überwiegend in den apikalen Abschnitten eine besondere Empfindlichkeit aufweisen. Mit Hilfe der Phasenkontrastmikroskopie und der von Engström entwickelten Oberflächenpräparationstechnik stellte Kohonen eine unterschiedliche Nervenversorgung der einzelnen Haarzellen fest. Die Verteilung der reich granulierten Nervenendigungen ließ eine Gesetzmäßigkeit erkennen. Die Zahl der granulierten Nervenendigungen nimmt z. B. bei den äußeren Haarzellen von der Basis zur Spitze hin und von der Inneren zur äußeren Reihe hin ab. In den gleichen Richtungen radial und linear zur Schneckenapitze verläuft auch die Degeneration der Haarzellen bei der Intoxikation. Nach Kohonen ist die Empfindlichkeit der Haarzellen gegenüber den toxischen Antibiotika direkt proportional der Zahl ihrer Nervenendigungen.

Kolde, Hala und Hando (1966) kamen auf Grund histochemischer Untersuchungen zu einem ähnlichen Ergebnis, wenn man unterstellt, daß die Innervation in einem engen Verhältnis zur Funktion und damit zur Stoffwechselintensität der Zelle steht. Auch bei diesen Untersuchungen fiel eine Korrelation zwischen der Stoffwechselaktivität der Haarzellen und ihrer Vulnerabilität auf. Die histochemisch durch ihren besonders hohen Succinatdehydrogenasegehalt sich auszeichnenden äußeren Haarzellen wiesen regelmäßig die ersten Veränderungen auf.

Diese Schädigungsfolge ist aber nicht nur charakteristisch für Streptomycin und die übrigen Antibiotika mit Oligosaccharidstruktur, sondern gilt nach den Untersuchungen Koldes und seiner Mitarbeiter genau so für Chloramphenicol und Chinin. Voraussetzung ist nur, daß die Substanzen unmittelbar an das Innenohr herangebracht werden. Kolde gab die toxischen Stoffe direkt in die Lückenöhle vor die dünne Membran des runden Fensters, damit sie von hier aus in hoher Konzentration in das Innenohr diffundieren können. Sogar O_2 Mangel, Ultraschall und Hochfrequenzstrom können wie Beck und Michler (1960) feststellten, das gleiche Schädigungsbild wie die Streptomycin-Antibiotika hervorrufen.

Nicht nur die Sinnesepithelien, sondern fast alle Zellen des Innenohres wie die Ganglienzellen, die Stützellen des Cortiorgans oder die Epithelien der *Stria vascularis* lassen früher oder später — einige Untersucher glauben sogar noch von den Haarzellen — Zeichen einer Schädigung erkennen. Dies spricht dafür, daß die Spezifität der Intoxikation nicht, wie immer wieder behauptet wird, auf einen einzigen Zelltyp, die Haarzellen, denen eine spezifische Empfindlichkeit zugeschrieben wird, beschränkt ist, sondern vielmehr auf das ganze Innenohrorgan zutrifft.

Mit Hilfe morphologischer und funktioneller Untersuchungsmethoden gelang es zwar, den Angriffspunkt und die Schädigungsfolgen zu bestimmen. Es muß jedoch Müsbeck zugestimmt werden, wenn er feststellt, daß die morphologische Technik ebenso wenig wie die funktionellen Prüfungen irgend eine Aussage über den eigentlichen Wirkungsmechanismus zulassen. Ja, daß sie teilweise sogar zu Fehlbeurteilungen geführt haben.

II Zur Pharmakologie und Toxikologie der ototoxischen Streptomyces-Antibiotika

1 Die Struktur der toxischen basischen Antibiotika

Abraham und Newton machten auf dem IV. Internationalen Kongreß für Biochemie den Vorschlag, die Antibiotika nach chemisch strukturellen Gesichtspunkten einzuteilen. Die toxischen Streptomycesantibiotika Streptomycin, Neomycin, Kanamycin, Paromomycin und einige weniger bekannte Verbindungen werden in dieser Einteilung als eine geschlossene Gruppe zusammengefaßt, die durch die Struktureinheit Zucker gekennzeichnet wird. In der Literatur wird auch häufig von den Antibiotika der Oligosaccharidgruppe oder den Aminoglykosidantibiotika gesprochen.

Andere Autoren bevorzugen die Bezeichnung „basische Streptomycesantibiotika“ (Mückter 1961) nicht nur weil die stark basische Eigenschaft ein charakteristisches Merkmal der ototoxischen Antibiotika darstellt, sondern weil darüber hinaus der Basizität auch eine besondere Bedeutung für die toxische Wirkungsweise beigegeben wird.

Alle Streptomycessubstanzen dieser Gruppe besitzen als gemeinsames Strukturmerkmal basische Hexosen, basische Cyclite, ringständige basische Gruppen und primäre Aminogruppen.

Die 3 Streptomyeine das Streptomycin (SM), Dihydrostreptomycin (DSM) und Dihydrodesoxystreptomycin (DDSM) unterscheiden sich von den anderen Streptomycesantibiotika der Oligosaccharidgruppe die zur sog. Neomycingruppe gerechnet werden, lediglich durch nicht basische Hexosen und eine Guanidinkomponente.

Zur Neomycingruppe zählen die in ihrer chemischen Struktur nahe verwandten Verbindungen, das Neomycin (NEO) und Kanamycin (KA) sowie das Paromomycin (PA) bzw. Aminosaline. An dem Namen Neomycingruppe wird mit Recht ausgedrückt, daß die Substanzen dieser Gruppe sehr verschiedene und vom Neomycin erheblich abweichende Eigenschaften aufweisen. Owada (1962) empfiehlt daher um Verwechslungen zu vermeiden,

statt Neomycingruppe die Bezeichnung „Deoxystreptaminhaltige Gruppe“.

Auffällig ist, wie auch Mückter in seiner Monographie hervorhebt, daß alle stark basischen Antibiotika neurotoxische Eigenschaften aufweisen. Da gilt nicht nur für die Streptomycessubstanzen der Oligosaccharidgruppe sondern auch für andere Antibiotika, z. B. die cyclischen Polypeptide wie Polymyxin B oder Polymyxin E (Colistin[®]) und das Circulin. Die letzten Antibiotika werden i. G. zu den Streptomycessubstanzen fermentell aus Bakterien gewonnen. Die cyclischen Polypeptide haben in ihrer chemischen Struktur zu den Antibiotika der Oligosaccharidgruppe abgesehen von den primären Aminogruppen, keine Beziehung. Colistin ist mit einem Molekulargewicht von 9676 ungefähr doppelt so schwer wie die Streptomycessubstanzen. Warum diese basischen Antibiotika mit Polypeptidstruktur im Gegensatz zu den basischen Streptomycessubstanzen nur

Haarzellen im Gegensatz zu den äußeren Zellen überwiegend in den apikalen Abschnitten eine besondere Empfindlichkeit aufweisen. Koide gab die toxischen Stoffe direkt in die Paukenhöhle vor die dünne Membran des runden Fensters, damit sie von hier aus in hoher Konzentration in das Innenohr diffundieren können. Sogar O-Mangel Ultraschall und Hochfrequenzstrom können, wie Beck und Miehler (1960) feststellten, das gleiche Schädigungsbild wie die Streptomycin-Antibiotika hervorrufen.

Nicht nur die Sinnesepithelien, sondern fast alle Zellen des Innenohres wie die Ganglienzellen, die Stützellen des Cortiorgans oder die Epithelien der Stria vascularis lassen früher oder später — einige Untersucher glauben sogar noch vor den Haarzellen — Zeichen einer Schädigung erkennen. Diese Tatsache spricht dafür, daß die Spezifität der Intoxikation nicht wie immer wieder behauptet wird, auf einen einzigen Zelltyp, die Haarzellen, denen eine spezifische Empfindlichkeit zugeschrieben wird, beschränkt ist, sondern vielmehr auf das ganze Innenohrorgan zutrifft.

Mit Hilfe morphologischer und funktioneller Untersuchungsmethoden gelang es zwar, den Angriffspunkt und die Schädigungsfolgen zu bestimmen. Es muß jedoch Mäsebeck zugestimmt werden, wenn er feststellt, daß die morphologische Technik ebenso wenig wie die funktionellen Prüfungen irgend eine Aussage über den eigentlichen Wirkungsmechanismus zulassen. Ja, daß sie teilweise sogar zu Fehlbeurteilungen geführt haben.

lamin ergaben. Bei den antagonistisch wirkenden, depolarisierenden Substanzen vom Typ des Succinylcholins fand sich entsprechend eine Abschwächung der relaxierenden Wirkung des Streptomycins.

Während der akute Vergiftungsmechanismus weitgehend erforscht zu sein scheint, sind unsere Kenntnisse über die spezifisch oto- und nephrotoxische Wirkung noch sehr lückenhaft und unsicher. Nach Mückters Ansicht ist die für die akute Vergiftung offenbar wesentliche Verminderung des Calciums bzw. seiner Ionisation für die spezifische Intoxikation wahr scheinlich ohne Bedeutung. Sie könnte eher mit den antienzymatischen Erscheinungen, wie sie bei der chronischen bzw. semichronischen Vergiftung beschrieben worden sind, in Zusammenhang gebracht werden.

Schon im Jahre 1949 wies Umbreit darauf hin, daß SM auf den sowohl für die Bakterienzelle als auch für die Zellen des Organismus gleichermaßen wichtigen Krebszyklus einen Einfluß hat. SM soll in die Reaktion Brenztraubensäure-Oxalacetat und damit in die energetische Versorgung zur Erhaltung der Struktur und Funktion der Zelle eingreifen.

Hauptenergiequelle für die Zelle sind die Kohlehydrate, die im Organismus stufenweise unter Mitwirkung von Enzymen abgebaut werden. Der Abbau erfolgt vom Glycogen bzw. der Glucose ausgehend durch Phosphorylierungsvorgänge über Triosephosphate bis zur Brenztraubensäure. Diese wird ebenso wie die Abbauprodukte des Eiweißes und der Fette über eine mehrstufige Reaktion, die über Thioester zur Bildung von Acetyl-Coenzym A führt, in den Zitronensäurezyklus eingeschleust. Hier erfolgt der weitere Abbau durch Oxydation und stufenweise Freisetzung der Energie.

Keller, Kräpe, Sosa und Mückter (1953) vermuteten bereits die Ursache für die Streptomycinschädigung in einer Störung des Coenzym-A-Systems. Diese Vorstellung fand durch die Untersuchungen von Mascielli-Corlandoli (1952) eine experimentelle Stütze. M. Mascielli-Corlandoli konnte unter SM, DSV und Neomycin in verschiedenen Organen, vor allem in den Mitochondrien eine Herabsetzung des Coenzym-A-Gehaltes nachweisen. Auf die Verminderung des Coenzym-A in der Nebennierenrinde ist nach seiner Ansicht auch die gestörte Corticosteroidsynthese zurückzuführen.

Die Hemmung der Nebennierenrindenfunktion läßt sich, das sei hier am Rande bemerkt, aber auch auf andere Weise erklären. Sie könnte ebenso gut durch eine direkte Konkurrenz der basischen Streptomycinantibiotika mit basischen Makromolekülen wie ACTH erklärt werden, eine Auffassung, die vor allem von Higginbotham und Dougherty (1957) vertreten wird.

Auf welche Weise Streptomycin das Coenzym A zu beeinflussen vermag, zeigen die Untersuchungen Liebsteins und Gillmans (1951). Danach hemmt SM die Synthese der Pantothensäure, die einen wichtigen Baustein des Coenzym A darstellt. Untersuchungen an Saccharomycesarten ergaben, daß SM die Verbindung von Pantoylacton mit β -Alanin verhindert.

Andererseits muß hier aber auch daran gedacht werden, daß die stark basischen Antibiotika direkt mit der Pantothensäure reagieren und es zur Bildung eines stabilen Streptomycin-Pantothensäurekomplexes kommt. Hier

neurotoxische Erscheinungen, aber niemals Ohrschädigungen hervorrufen, stellt ein interessantes Phänomen dar das uns veranlaßt diese Substanzen mit in unsere Untersuchungen einzubeziehen

2 Die toxische Wirkung

Hinsichtlich der Ototoxizität der basischen Streptomycesantibiotika läßt sich folgende Reihenfolge aufstellen. Die geringste toxische Wirkung besitzt offensichtlich Streptomycin, danach folgen Dihydrostreptomycin, Viomycin, Kanamycin, Paromomycin, Framycetin, schließlich Gentamycin und als stärkste toxische Verbindung dieser Gruppe das Neomycin.

Bei der Streptomycinintoxikation wird grundsätzlich zwischen einer akuten Vergiftung, der chronischen Intoxikation und organspezifischer Wirkung unterschieden. Die akute Toxizität der Aminoglykosidantibiotika soll hier nur am Rande betrachtet werden, da sie mehr von theoretischem Interesse, für die Praxis wahrscheinlich aber bedeutungslos ist. Akute Vergiftungen treten in den meisten Fällen nur bei intravenöser und intrathekalen Applikation oder bei intramuskulärer Injektion extrem hoher Dosen in Erscheinung. Sie äußern sich zunächst in Erregungszuständen und Konvulsionen, die in wenigen Minuten in eine allgemeine Lähmung der quergestreiften Muskulatur übergehen und schließlich zum Atemstillstand und Exitus letalis führen können. Vom klinischen Standpunkt aus gesehen handelt es sich hier um das Symptomenbild einer Magnesiumvergiftung. Die meisten Magnesiumeffekte beruhen aber im Grunde genommen auf einer Verdrängung der Calciumionen (Hausehold, 1959). Auch der akuten Streptomycinintoxikation scheint ursächlich ein calciumprivier Effekt zugrunde zu liegen, wofür z. B. auch die Störung der Blutgerinnung spricht. Jones (1959) gelang es, die neuromuskulären Symptome bei der Behandlung solcher Patienten mit Neomycin durch Calciumgaben günstig zu beeinflussen. Nach Keller *et al.* (1950) sollen die basischen Streptomycesantibiotika eine besondere Affinität zu den Calciumionen besitzen. Tatsächlich konnte auch unter Streptomycin eine Verminderung des ionisierten Calciums bei unverändertem Gesamtcalciumgehalt nachgewiesen werden.

Durch Calciummangel kommt es, wie bereits Harvey und Macintosh (1930) feststellten, zu einer Störung der Erregungsübertragung und zu Lähmungen, die auf einem Aussetzen der Acetylcholinbildung am Nervenende beruhen sollen. Schaefer (1940) führt die herabgesetzte Erregbarkeit auf eine erhöhte Irmembrabilität der Membranen infolge des Ca-Mangels zurück. Auf die Bedeutung der Calciumionen für das Membranpotential weist auch Brink hin. Die Ca-Verarmung hat einen neuromuskulären Block zur Folge, der klinisch wie eine Curarerelaxation imponiert und darum auch als curareähnliche Lähmung bezeichnet wird. Für einen solchen curareähnlichen Effekt der Aminoglykosidantibiotika sprechen auch die Befunde von Iwatsuki, Ueda und Yamada (1960) sowie Füllmann und Reuter (1960), die am Hund bzw. an der Ratte unter Streptomycin eine verstärkte Wirkung der repolarisationshemmenden Relaxantien d-Tubocurarin und Cal

der Lage ist, die toxische Wirkung des Streptomycins weder am Hör- noch am Gleichgewichtsorgan aufzuheben oder auch nur zu vermindern.

Mückter (1961) setzt sich in seiner Monographie eingehend mit den Möglichkeiten einer Entgiftung und den widersprechenden Befunden auseinander. In einer neueren Arbeit (Mückter 1966) wendet er sich gegen die vor kurzem wiederum von Kuschinsky (1966) geäußerte Ansicht, die Pantothenensäure besäße keine entgiftende Wirkung. Mückter bemüht sich richtigzustellen, daß von seiner Seite niemals behauptet worden sei, die Pantothenensäure verhindere ototoxische Schädigungen. Pantothenensäure soll, so wird ausdrücklich betont, lediglich die Toleranz des Antibiotikums verbessern. Mückter verweist hier allein auf 59 teils experimentelle, teils klinische Arbeiten, die übereinstimmend für eine solche verbesserte Toleranz sprechen, während nur in 16 Arbeiten der Pantothenäureeffekt nicht reproduziert werden konnte. Die Befürworter der Pantothenensäure können sich vor allem auf neuere Arbeiten berufen, die, verglichen mit älteren Untersuchungen aus den 50er Jahren, zu denen auch die Arbeiten von Kuschinsky, Löffmann und Pracht zu rechnen sind, unter verbesserten Versuchsbedingungen durchgeführt wurden. Besonders die elektrophysiologischen Untersuchungen Tybergheles und der Arbeitsgruppe Keidel, auf die bereits eingegangen wurde, werden hier hervorgehoben. Mit Hilfe histochemischer Methoden konnte auch Müsebeck unter Pantothenensäure eine Herabsetzung der Streptomycintoxizität um etwa ein Drittel feststellen. Gegenteilige Berichte kommen, wie Müsebeck sehr richtig bemerkt, zum Teil dadurch zustande, daß die gewählte Dosis bereits über diesem Drittel der toxischen Grenzdosis liegt, so daß die Heraufsetzung der Verträglichkeitsgrenze durch die Pantothenensäure nicht mehr zu erkennen ist. Besonders manchen experimentellen Arbeiten, so glaubt Müsebeck, in denen SM bewußt zur Erzeugung einer toxischen Reaktion weitläufiger dosiert wurde, liegt dieser Trugschluß einer angeblich fehlenden Schutzwirkung der Pantothenate zugrunde.

Nach Mückters Ansicht sind von den zahlreichen Substanzen, denen eine Herabsetzung der Toxizität bzw. eine toleranzverbessernde Wirkung zugeschrieben wird, nur das Calcium bei der akuten Vergiftung, im übrigen vor allem aber die Pantothenensäure und wie sich in letzter Zeit zeigte, angeblich auch die Methansulfonatsalze der Streptomycinsantibiotika sicher wirksam.

Dagegen haben alle anderen Vorschläge zur Toxizitätsminderung des Streptomycins keine praktische Bedeutung erlangt. So wurden neben der Pantothenensäure auch noch andere Vitamine wie Ascorbinsäure, Nikotinsäure, p-Aminobenzoesäure, Vitamin A und Lactoflavin empfohlen.

Eine weitere Gruppe sog. entgiftender Substanzen stellen die sauren Mucopolysaccharide wie Heparin und die Heparinoide dar (Higginbotham und Dougherty 1957, Mückter 1961). Man nimmt heute allgemein an, daß die stark basischen Antibiotika als Kationen mit sauren anionischen Gruppen verschiedenster Art, z. B. wie wir eben gesehen haben mit der Pantothensäure

durch wird dem Organismus die für die Coenzym A-Synthese notwendige Pantothenensäure entzogen. Die toxischen Störungen, die durch Streptomycin hervorgerufen werden, gleichen tatsächlich in mancher Hinsicht dem Symptomenbild eines Pantothenensäuremangels. Die Entdeckung Kellers und seiner Mitarbeiter (1955, 1956, 1956) daß durch Zusatz von Pantothenensäure die Toxizität des SM herabgesetzt werden kann, wurde ebenfalls gut in diese Vorstellungen hineinpassen.

Die Diskussion über die angeblich toxizitätsmindernde Eigenschaft der Pantothenensäure ist bis heute noch in vollem Gange. Die Befunde Kellers und seiner Mitarbeiter, denen man für die praktische Anwendung der Streptomycinsantibiotika große Bedeutung beigemessen hat, wurden in der Folgezeit von zahlreichen Untersuchern sowohl für die akute als auch für die chronische Vergiftung nachgeprüft und bestätigt gefunden. Vor allem sollen die ototoxischen Erscheinungen durch Pantothenensäure günstig beeinflußt werden (Keller, Krüpe, Sons und Mückter 1955, 1956, 1956; Marquardt und Ziegler 1956; Ducrot, Leau und Cosar 1956; Neumann und Neubert 1958, und viele andere).

Zu erwähnen sind vor allem die neueren Arbeiten der letzten Jahre von Tjebbergheijn (1961, 1962), Müsebeck (1964) sowie Hattig und Keldel (1965), die mit verbesserten Untersuchungsmethoden durchgeführt wurden. Die geringere Toxizität einiger Pantothenatverbindungen konnte nicht nur im Tierexperiment demonstriert werden, sondern ließ sich auch beim Menschen nachweisen (Penman, Dickson und Miller 1957; Willemot, Coxsens, Pannier van der Calseide 1959; Slevers, 1960 sowie Eckel und Altenburger 1960 u. a.).

Tjebbergheijn verglich den Einfluß der verschiedenen Streptomycinsubstanzen, ihrer Sulfat-, Mono-, Di- und Tripanthensalze auf die Mikrophonpotentiale der Meerschweinchenschnecke. Er fand nicht nur bei den Sulfaten, sondern auch bei den Pantothenatverbindungen eine Abnahme der Mikrophonpotentiale, insbesondere in den hohen Frequenzen. Nur die Streptomycinolipantothenate und Kanamycinmonopantothenate riefen beim Meerschweinchen keine meßbaren Hörstörungen hervor. Zu dem gleichen Ergebnis kamen auch Hattig und Keldel, die elektrophysiologische Untersuchungen an der Katze durchführten. Sie stellten fest, daß von allen untersuchten Substanzen Kanamycinmonopantothenat das Hörorgan am wenigsten schädigt.

Die Bedeutung der Pantothenensäure für die Entgiftung der Streptomycinsantibiotika blieb jedoch nicht ohne Widerspruch. Osterberg und Mitarbeiter (1956/57) fanden lediglich eine geringere cochleotoxische Wirkung, aber keinen Einfluß auf die Vestibularisstörungen. Zu vollständig negativen Ergebnissen kamen dagegen Kummerle und Gosswald (1956), Hawkins, Wolcott und O'Shanny (1956/57), Child, Davis, Sharpe und T. Mich (1956/57), Clorig (1958), Brigham und Nielsen (1958), Des Autels (1959), Kuschinsky, Lüllmann und Tracht (1960) sowie Wersäll und Hawkins (1962). Sie stellen übereinstimmend fest, daß die Pantothenensäure nicht in

der Lage ist, die toxische Wirkung des Streptomycins weder am Hör- noch am Gleichgewichtsorgan aufzuheben oder auch nur zu vermindern.

Mückter (1961) setzt sich in seiner Monographie eingehend mit den Möglichkeiten einer Entgiftung und den widersprechenden Befunden auseinander. In einer neueren Arbeit (Mückter 1966) wendet er sich gegen die vor kurzem wiederum von Kuschinsky (1966) geäußerte Ansicht, die Pantothenensäure besäße keine entgiftende Wirkung. Mückter bemüht sich richtigzustellen, daß von seiner Seite niemals behauptet worden sei, die Pantothenensäure verhindere ototoxische Schädigungen. Pantothenensäure soll, so wird ausdrücklich betont, lediglich die Toleranz des Antibiotikums verbessern. Mückter verweist hier allein auf 59 teils experimentelle, teils klinische Arbeiten, die übereinstimmend für eine solche verbesserte Toleranz sprechen, während nur in 16 Arbeiten der Pantothenäureeffekt nicht reproduziert werden konnte. Die Befürworter der Pantothenensäure können sich vor allem auf neuere Arbeiten berufen, die, verglichen mit älteren Untersuchungen aus den 50er Jahren, zu denen auch die Arbeiten von Kuschinsky, Lüllmann und Pracht zu rechnen sind, unter verbesserten Versuchsbedingungen durchgeführt wurden. Besonders die elektrophysiologischen Untersuchungen Tybergheins und der Arbeitsgruppe Keldel, auf die bereits eingegangen wurde, werden hier hervorgehoben. Mit Hilfe histochemischer Methoden konnte auch Müsebeck unter Pantothenensäure eine Herabsetzung der Streptomycintoxizität \pm um etwa ein Drittel feststellen. Gegenteilige Berichte kommen, wie Müsebeck sehr richtig bemerkt, zum Teil dadurch zustande, daß die gewählte Dosis bereits über diesem Drittel der toxischen Grenzdosis liegt, so daß die Heraufsetzung der Verträglichkeitsgrenze durch die Pantothenensäure nicht mehr zu erkennen ist. Besonders manchen experimentellen Arbeiten, so glaubt Müsebeck, in denen SM bewußt zur Erzeugung einer toxischen Reaktion weitaus höher dosiert wurde, liegt dieser Trugschluß einer angeblich fehlenden Schutzwirkung der Pantothenate zugrunde.

Nach Mückters Ansicht sind von den zahlreichen Substanzen, denen eine Herabsetzung der Toxizität bzw. eine toleranzverbessernde Wirkung zugeschrieben wird, nur das Calcium bei der akuten Vergiftung, im übrigen vor allem aber die Pantothenensäure und wie sich in letzter Zeit zeigte, angeblich auch die Methansulfonatsalze der Streptomycesan antibiotika sicher wirksam.

Dagegen haben alle anderen Vorschläge zur Toxizitätsminderung des Streptomycins keine praktische Bedeutung erlangt. So wurden neben der Pantothenensäure auch noch andere Vitamine wie Ascorbinsäure, Nikotinsäure, p-Aminobenzoessäure, Vitamin A und Lactoflavin empfohlen.

Eine weitere Gruppe sog. entgiftender Substanzen stellen die sauren Mucopolysaccharide wie Heparin und die Heparinoide dar (Higginbotham und Dougherty 1937; Mückter 1961). Man nimmt heute allgemein an, daß die stark basischen Antibiotika als Kationen mit sauren anionischen Gruppen verschiedenster Art, z. B. wie wir eben gesehen haben mit der Pantothen-

säure oder der Ascorbinsäure so auch hier mit dem sauren Heparin eine Verbindung eingehen können. Aronson, Meyer und Brock (1964) befaßten sich eingehend mit den Reaktionsmöglichkeiten des Streptomycins. Auf welche Weise das Kation SM mit den verschiedenen Verbindungen, wie Hyaluronsäure, Cephalin, Casein u. a. reagiert, ob als Carbinolamin oder als Iminiumsalz, läßt sich danach noch nicht mit Sicherheit sagen.

Die Tatsache, daß die kationischen basischen Antibiotika eine besondere Affinität zu den sauren anionischen Substanzen besitzen, ließ sich experimentell beweisen. Durch Versuche *in vitro* konnte gezeigt werden, daß sich Heparin mit den Streptomycinsantibiotika verbindet, wobei es zu einer echten Präzipitation kommt. Wie Mora, Young und Shear (1959) feststellen, werden nicht nur die Basen Streptomycin und Neomycin, sondern auch andere basische Substanzen, wie die Polymyxine oder das Prolamin durch anionische Polyglucosederivate gebunden und dadurch entgiftet. Umgekehrt kann die Toxizität der basischen Antibiotika durch andere basische Makromoleküle wie ACTH gesteigert werden, indem diese in Konkurrenz mit den toxischen Antibiotika die sauren Substanzen des Organismus, die sonst zur Entgiftung beitragen, beschlagnahmen (Higginbotham und Dougherty 1957).

Von der besonderen Affinität der basischen Streptomycinsubstanzen zu den sauren Mucopolysacchariden geht auch Müsebeck's Theorie (1964) über die ototoxische Wirkungsweise des Streptomycins aus. In einer früheren Arbeit hatten bereits Müsebeck und Schützle (1962) auf die Abnahme der sauren Mucopolysaccharide im Ligamentum spirale und im Imbus spiralis aufmerksam gemacht. Als erstes Zeichen einer toxischen Schädigung beobachtete Müsebeck eine Veränderung in den proteingebundenen Sulfhydraten im Bereich der Stria vascularis des Innenohrs. Aus diesen histochemischen Befunden schließt Müsebeck, daß die toxischen Antibiotika wahrscheinlich nicht gleichmäßig im Innenohr verteilt sind, sondern hier bevorzugte Angriffspunkte und Retentionsorte besitzen. Derartige bevorzugte Retentionsorte werden z. B. in dem mucopolysaccharidreichen Bindegewebe der Stria vascularis vermutet. Von diesen Speicherräumen aus soll nach Ansicht Müsebeck's erst sekundär eine Schädigung der umgebenen Zellen, insbesondere des Sinnesepithels, erfolgen.

In jüngster Zeit sind allerdings Zweifel geäußert worden, ob die mit histochemischen Methoden nachgewiesenen Sulfhydratgruppen mit den sauren Mucopolysacchariden identisch sind. Lural (1965) konnte bei polarisationsmikroskopischen Untersuchungen weder in der Stria vascularis noch in der Membrana tectoria die bisher als besonders mucopolysaccharidreich angesehen wurde, saure Mucopolysaccharide nachweisen. Demnach müssen wahrscheinlich bei den Untersuchungen Müsebeck's auch noch andere saure Substanzen in Betracht gezogen werden, mit denen Streptomycin im Innenohr zu reagieren vermag. Higginbotham sah bei den basischen Antibiotika vom Typ des Polymyxins und Morikubo bei Kanamycin eine Affinität zu den sauren Substraten des ZNS. Diese Reaktion kann

offenbar für alle Antibiotika der Aminoglykosidgruppe nicht nur im ZNS, sondern auch zu anderen sauren Verbindungen des Organismus angenommen werden.

Auf ähnliche Weise wie die sauren Mucopolysaccharide sollen auch Aminosäuren wie Leucin, Glycin oder Methionin mit den basischen Antibiotika reagieren und dadurch entgiftend wirken. Wahrscheinlich entstehen hier ebenfalls stabile, komplexe Verbindungen zwischen dem Antibiotikum und der Aminosäure, die die Reaktionsfähigkeit der toxischen Substanz herabsetzen.

Cohen berichtete 1946, daß Streptomycin auch mit den Nukleinsäuren der Bakterienzelle reagiert. Diese Wirkung ist offenbar nicht nur auf die Bakterienzelle beschränkt, sondern scheint nach den Untersuchungen von Floberg, Hamberger und Hyden (1949) ebenso die Zellen des Organismus zu betreffen. Mit Hilfe der UV-Mikrospektrographie konnte man unter SM eine Verminderung des Nukleinsäuregehaltes der Nervenzellen, vor allem im Ganglion vestibulare nachweisen.

Die Tatsache, daß SM eine besondere Affinität zu den Nukleinsäuren nicht nur der Bakterien- sondern auch der Körperzellen besitzt, weist auf eine enge Beziehung zwischen dem toxischen und antibiotischen Wirkungsmechanismus hin. Wahrscheinlich beruhen beide auf dem gleichen Prinzip. Man muß sich dann fragen, ob eine Entgiftung des Streptomycins z. B. durch Kopplung an saure Substanzen wie Pantothensäure, Ascorbinsäure, Heparin, Aminosäuren oder Nukleinsäuren nicht gleichzeitig eine Herabsetzung der antibiotischen Wirksamkeit zur Folge hat.

Morikubo, Iwasaki, Takeuchi, Hukiji und Umezawa (1959) stellten bereits fest, daß durch die Bindung des Kanamycins an saure Phosphoproteine nicht nur die toxische Eigenschaft, sondern auch der antibiotische Effekt weitgehend aufgehoben werden.

Zu einem ähnlichen Ergebnis führte auch eine genauere Untersuchung der angeblich entgiftenden Wirkung der Ascorbinsäure, die von Prescott, Kaufmann, James und Storr (1959) und nochmals 1962 von Kralj empfohlen wurde. Lagler und Sous (1960) konnten den Nachweis erbringen, daß die Ursache der geringeren Toxizität unter dem Einfluß der Ascorbinsäure auf einer Herabsetzung des Streptomycinblutspiegels beruht. Sie injizierten Ratten Kanamycin und zum Vergleich einer anderen Gruppe Kanamycin zusammen mit Na-Ascorbinsäure. Es zeigte sich, daß der Kanamycinblutspiegel durch Ascorbinsäure um 50% herabgesetzt wird. Bei Meeresschildkröten war dieser Effekt weniger stark ausgeprägt. Ascorbinsäure verminderte hier die Blutkonzentration nur um 20%. In diesem Fall stellt also die Toxizitätsminderung des Kanamycins keine Entgiftung im eigentlichen Sinne dar, sondern lediglich eine allgemeine Wirkungsaminderung des Antibiotikums und zwar sowohl in toxischer als auch in antibiotischer Hinsicht. Der gleiche Effekt läßt sich aber genau so gut durch eine geringere Dosierung des Antibiotikums erzielen.

Auch die Antihistaminika erwiesen sich im Hinblick auf eine Entgiftung

säure oder der Ascorbinsäure so auch hier mit dem sauren Heparin eine Verbindung eingehen können Aronson, Meyer und Brock (1961) befaßten sich eingehend mit den Reaktionsmöglichkeiten des Streptomycins Auf welche Weise das Kation SM mit den verschiedenen Verbindungen wie Hyaluronsäure, Cephalin, Casein u. a. reagiert, ob als Carbinolamin oder als Iminiumsalz, läßt sich danach noch nicht mit Sicherheit sagen.

Die Tatsache, daß die kationischen basischen Antibiotika eine besondere Affinität zu den sauren anionischen Substanzen besitzen, ließ sich experimentell beweisen. Durch Versuche *in vitro* konnte gezeigt werden, daß sich Heparin mit den Streptomycinsantibiotika verbindet, wobei es zu einer echten Präzipitation kommt. Wie Nora Young und Shear (1960) feststellten, werden nicht nur die Basen Streptomycin und Neomycin, sondern auch andere basische Substanzen wie die Polymyxine oder das Protamin durch anionische Polyglucosederivate gebunden und dadurch entgiftet. Umgekehrt kann die Toxizität der basischen Antibiotika durch andere basische Makromoleküle wie ACTH gesteigert werden, indem diese in Konkurrenz mit den toxischen Antibiotika die sauren Substanzen des Organismus, die sonst zur Entgiftung beitragen, beschlagnahmen (Higginbotham und Dougherty 1957).

Von der besonderen Affinität der basischen Streptomycinsubstanzen zu den sauren Mucopolysacchariden geht auch Müsebeck's Theorie (1964) über die ototoxische Wirkungsweise des Streptomycins aus. In einer früheren Arbeit hatten bereits Müsebeck und Schatzle (1962) auf die Abnahme der sauren Mucopolysaccharide im Ligamentum spirale und im Limbus spiralis aufmerksam gemacht. Als erstes Zeichen einer toxischen Schädigung beobachtete Müsebeck eine Veränderung in den proteingebundenen Sulfhydrylen im Bereich der Stria vascularis des Innenohres. Aus diesen histochemischen Befunden schließt Müsebeck, daß die toxischen Antibiotika wahrscheinlich nicht gleichmäßig im Innenohr verteilt sind, sondern hier bevorzugte Angriffspunkte und Retentionsorte besitzen. Derartige bevorzugte Retentionsorte werden z. B. in dem mucopolysaccharidreichen Bindegewebe der Stria vascularis vermutet. Von diesen Speichersorten aus soll nach Ansicht Müsebeck's erst sekundär eine Schädigung der umliegenden Zellen, insbesondere des Sinnesepithels, erfolgen.

In jüngster Zeit sind allerdings Zweifel geäußert worden, ob die mit histochemischen Methoden nachgewiesenen Sulfhydrylgruppen mit den sauren Mucopolysacchariden identisch sind. Iurato (1964) konnte bei polarisationsmikroskopischen Untersuchungen weder in der Stria vascularis noch in der Membrana tectoria die bisher als besonders mucopolysaccharidreich angesehen wurde, saure Mucopolysaccharide nachweisen. Demnach müssen wahrscheinlich bei den Untersuchungen Müsebeck's auch noch andere saure Substanzen in Betracht gezogen werden, mit denen Streptomycin im Innenohr zu reagieren vermag. Higginbotham kam bei den basischen Antibiotika vom Typ des Polymyxins und Morikawa bei Kanamycin eine Affinität zu den sauren Substraten des ZNS. Diese Reaktion kann

offenbar für alle Antibiotika der Aminoglykosidgruppe nicht nur im ZNS, sondern auch zu anderen sauren Verbindungen des Organismus angenommen werden.

Auf ähnliche Weise wie die sauren Mucopolysaccharide sollen auch Aminosäuren wie Leucin, Glycin oder Methionin mit den basischen Antibiotika reagieren und dadurch entgiftend wirken. Wahrscheinlich entstehen hier ebenfalls stabilere, komplexe Verbindungen zwischen dem Antibiotikum und der Aminosäure die die Reaktionsfähigkeit der toxischen Substanz herabsetzen.

Cohen berichtete 1946, daß Streptomycin auch mit den Nukleinsäuren der Bakterienzelle reagiert. Diese Wirkung ist offenbar nicht nur auf die Bakterienzelle beschränkt, sondern scheint nach den Untersuchungen von Floberg, Hamberger und Hyden (1949) ebenso die Zellen des Organismus zu betreffen. Die Tatsache, daß SM eine besondere Affinität zu den Nukleinsäuren nicht nur der Bakterien sondern auch der Körperzellen besitzt, weist auf eine enge Beziehung zwischen dem toxischen und antibiotischen Wirkungsmechanismus hin. Wahrscheinlich beruhen beide auf dem gleichen Prinzip. Man muß sich darum fragen, ob eine Entgiftung des Streptomycins z. B. durch Kopplung an saure Substanzen wie Pantothensäure, Ascorbinsäure, Heparin, Aminosäuren oder Nukleinsäuren nicht gleichzeitig eine Herabsetzung der antibiotischen Wirksamkeit zur Folge hat.

Morikubo, Yamazaki, Takenchi, Hikiji und Umetawa (1959) stellten bereits fest, daß durch die Bindung des Kanamycins an saure Phosphoproteine nicht nur die toxische Eigenschaft, sondern auch der antibiotische Effekt weitgehend aufgehoben werden.

Zu einem ähnlichen Ergebnis führte auch eine genauere Untersuchung der angeblich entgiftenden Wirkung der Ascorbinsäure, die von Prescott, Kaufmann, James und Stone (1959) und nochmals 1962 von Arzhl empfohlen wurde. Lagler und Sousa (1965) konnten den Nachweis erbringen, daß die Ursache der geringeren Toxizität unter dem Einfluß der Ascorbinsäure auf einer Herabsetzung des Streptomycinblutspiegels beruht. Sie injizierten Ratten Kanamycin und zum Vergleich einer anderen Gruppe Kanamycin zusammen mit Na-Ascorbinat. Es zeigte sich, daß der K_{a} Blutspiegel durch Ascorbinsäure um 50% herabgesetzt wird. Bei Meerschweinchen war dieser Effekt weniger stark ausgeprägt, Ascorbinsäure verminderte hier die Blutkonzentration nur um 20%. In diesem Fall stellt also die Toxizitätsminderung des Kanamycins keine Entgiftung im eigentlichen Sinne dar sondern lediglich eine allgemeine Wirkungsminderung des Antibiotikums und zwar sowohl in toxischer als auch in antibiotischer Hinsicht. Der gleiche Effekt läßt sich aber genau so gut durch eine geringere Dosierung des Antibiotikums erzielen.

Auch die Antiblastaminiaka erwiesen sich im Hinblick auf eine Entgiftung

saure oder der Ascorbinsäure so auch hier mit dem sauren Heparin eine Verbindung eingehen können. Aronson, Meyer und Brock (1964) befaßten sich eingehend mit den Reaktionsmöglichkeiten des Streptomycins. Auf welche Weise das Kation SM mit den verschiedenen Verbindungen wie Hvaluronsäure, Cephalin, Casein u. a. reagiert, ob als Carbinolamin oder als Iminiumsalz, läßt sich danach noch nicht mit Sicherheit sagen.

Die Tatsache, daß die kationischen basischen Antibiotika eine besondere Affinität zu den sauren anionischen Substanzen besitzen, ließ sich experimentell beweisen. Durch Versuche *in vitro* konnte gezeigt werden, daß sich Heparin mit den Streptomycinsantibiotika verbindet, wobei es zu einer echten Präzipitation kommt. Wie Mora, Young und Shear (1959) feststellten, werden nicht nur die Basen Streptomycin und Neomycin, sondern auch andere basische Substanzen, wie die Polymyxine oder das Tretamin, durch anionische Polyglucosederivate gebunden und dadurch entgiftet. Umgekehrt kann die Toxizität der basischen Antibiotika durch andere basische Makromoleküle wie ACTH gesteigert werden, indem diese in Konkurrenz mit den toxischen Antibiotika die sauren Substanzen des Organismus, die sonst zur Entgiftung beitragen, beschlagnehmen (Higginbotham und Dougherty 1957).

Von der besonderen Affinität der basischen Streptomycinsubstanzen zu den sauren Mucopolysacchariden geht auch Müsebeck's Theorie (1964) über die ototoxische Wirkungsweise des Streptomycins aus. In einer früheren Arbeit hatten bereits Müsebeck und Schätzle (1962) auf die Abnahme der sauren Mucopolysaccharide im Ligamentum spirale und im Limbus spiralis aufmerksam gemacht. Als erstes Zeichen einer toxischen Schädigung beobachtete Müsebeck eine Veränderung in den proteingebundenen Sulfhydrylen im Bereich der Stria vascularis des Innenohres. Aus diesen histochemischen Befunden schließt Müsebeck, daß die toxischen Antibiotika wahrscheinlich nicht gleichmäßig im Innenohr verteilt sind, sondern hier bevorzugte Angriffspunkte und Retentionsorte besitzen. Derartige bevorzugte Retentionsorte werden z. B. in dem mucopolysaccharidreichen Bindegewebe der Stria vascularis vermutet. Von diesen Speicherungsorten aus soll nach Ansicht Müsebeck's erst sekundär eine Schädigung der umgebenden Zellen, insbesondere des Sinnesepithels, erfolgen.

In jüngster Zeit sind allerdings Zweifel geäußert worden, ob die mit histochemischen Methoden nachgewiesenen Sulfhydrylgruppen mit den sauren Mucopolysacchariden identisch sind. Iurato (1964) konnte bei polarisationsmikroskopischen Untersuchungen weder in der Stria vascularis noch in der Membrana tectoria die bisher als besonders mucopolysaccharidreich angesehen wurde, saure Mucopolysaccharide nachweisen. Demnach müssen wahrscheinlich bei den Untersuchungen Müsebeck's auch noch andere saure Substanzen in Betracht gezogen werden, mit denen Streptomycin im Innenohr zu reagieren vermag. Higginbotham sah bei den basischen Antibiotika vom Typ des Polymyxins und Mikado bei Kanamycin eine Affinität zu den sauren Substraten des ZNS. Diese Reaktion kann

offenbar für alle Antibiotika der Aminoglykosidgruppe nicht nur im ZNS, sondern auch zu anderen sauren Verbindungen des Organismus angenommen werden.

Auf ähnliche Weise wie die sauren Mucopolysaccharide sollen auch Aminosäuren wie Leucin, Glycin oder Methionin mit den basischen Antibiotika reagieren und dadurch entgiftend wirken. Wahrscheinlich entstehen hier ebenfalls stabilere komplexe Verbindungen zwischen dem Antibiotikum und der Aminosäure, die die Reaktionsfähigkeit der toxischen Substanz herabsetzen.

Cohen berichtete 1946, daß Streptomycin auch mit den Nukleinsäuren der Bakterienzelle reagiert. Diese Wirkung ist offenbar nicht nur auf die Bakterienzelle beschränkt, sondern scheint nach den Untersuchungen von Floberg, Hamberger und Hyden (1949) ebenso die Zellen des Organismus zu betreffen. Mit Hilfe der UV Mikrospektrographie konnte man unter SM eine Verminderung des Nukleinsäuregehaltes der Nervenzellen, vor allem im Ganglion vestibulare nachweisen.

Die Tatsache, daß SM eine besondere Affinität zu den Nukleinsäuren nicht nur der Bakterien- sondern auch der Körperzellen besitzt, weist auf eine enge Beziehung zwischen dem toxischen und antibiotischen Wirkungsmechanismus hin. Wahrscheinlich beruhen beide auf dem gleichen Prinzip. Man muß sich darum fragen, ob eine Entgiftung des Streptomycins z. B. durch Kopplung an saure Substanzen wie Pantothensäure, Ascorbinsäure, Heparin Aminosäuren oder Nukleinsäuren nicht gleichzeitig eine Herabsetzung der antibiotischen Wirksamkeit zur Folge hat.

Morikubo, Yamazaki, Takeuchi, Hikiji und Umesawa (1959) stellten bereits fest, daß durch die Bindung des Kanamycins an saure Phosphoproteine nicht nur die toxische Eigenschaft sondern auch der antibiotische Effekt weitgehend aufgehoben werden.

Zu einem ähnlichen Ergebnis führte auch eine genauere Untersuchung der angeblich entgiftenden Wirkung der Ascorbinsäure, die von Prescott, Kaufmann, James und Stone (1959) und nochmals 1962 von Krahel empfohlen wurde. Lagier und Sous (1963) konnten den Nachweis erbringen, daß die Ursache der geringeren Toxizität unter dem Einfluß der Ascorbinsäure auf einer Herabsetzung des Streptomycinblutspiegels beruht. Sie injizierten Ratten Kanamycin und zum Vergleich einer anderen Gruppe Kanamycin zusammen mit Na-Ascorbinat. Es zeigte sich, daß der Kanamycinblutspiegel durch Ascorbinsäure um 50% herabgesetzt wird. Bei Meerschweinchen war diese Effekt weniger stark ausgeprägt. Ascorbinsäure verminderte hier die Blutkonzentration nur um 20%. In diesem Fall stellt also die Toxizitätsminderung des Kanamycins keine Entgiftung im eigentlichen Sinne dar sondern lediglich eine allgemeine Wirkungsminde rung des Antibiotikums und zwar sowohl in toxischer als auch in antibiotischer Hinsicht. Der gleiche Effekt läßt sich aber genau so gut durch eine geringere Dosierung des Antibiotikums erzielen.

Auch die Antihistaminika erwiesen sich im Hinblick auf eine Entgiftung

lung des Streptomycins als unwirksam (Mückter 1961). Sie haben wahrscheinlich nur einen Einfluß auf die allergischen Nebenreaktionen, nicht aber auf die Ototoxizität des SM. Allergische Reaktionen wurden vor allem früher bei ungereinigten Präparaten sehr häufig beobachtet und kommen heute nur noch selten vor. Daneben muß aber auch berücksichtigt werden, daß SM selbst ebenfalls die Eigenschaft eines Histaminliberators besitzt. Radenbach und Amann (1959) konnten zeigen, daß es unter SM und DSM zu einer Freisetzung endogenen Histamins aus den Mastzellen kommt. Hier auf sind wahrscheinlich auch die gelegentlich zu beobachtenden Schmerzen an der Injektionsstelle sowie die juckenden Hautsensationen und Parästhesien zurückzuführen. Es wurde schon die Vermutung geäußert, daß die allergischen Erscheinungen Vorläufer der Intoxikation darstellen. Die Mehrzahl der Untersucher ist jedoch der Auffassung, daß zwischen der SM-Allergie und der SM-Vergiftung, insbesondere der Ototoxikose, keine Beziehung besteht. Andernfalls müßte mit den Antihistaminika eine Toxizitätsminderung zu erzielen sein, was aber nach den Untersuchungen Lagers und seiner Mitarbeiter offensichtlich nicht der Fall ist.

Zusammenfassend kann man sagen: liegt den bisher betrachteten toxischen Reaktionen ein gemeinsames Prinzip zugrunde. Danach reagieren die stark basischen Streptomycinsantibiotika als Kationen mit sauren anionischen Substanzen des Organismus bzw. auch der Bakterien. Hierdurch entsteht so ist wenigstens die Ansicht der meisten Untersucher ein Mangel z. B. an ionisiertem Calcium, an Pantothen-säure Coenzym A und anderen Enzymen, an Aminosäuren oder Nukleinsäuren. Der Entzug lebensnotwendiger Substanzen wird für die toxische, aber auch für die antibiologische Wirkung ursächlich verantwortlich gemacht. Es lag nahe, durch Zusatz der genannten sauren Verbindungen zu versuchen, die Toxizität herabzusetzen. Dieses Verfahren hat jedoch den Nachteil, daß hierdurch in den meisten Fällen auch die antibiologische Wirkung blockiert wird.

Es erscheint jedoch zu einseitig, wollte man ausschließlich die basischen und kationischen Eigenschaften für die Toxizität der toxischen Streptomycinsantibiotika verantwortlich machen. Daneben müssen auch noch andere charakteristische Merkmale in Betracht gezogen werden. Hauschild (1959) weist vor allem auf die Bedeutung der eigentümlichen Aminosäuregruppe hin, die diese Antibiotika kennzeichnet. Man stellt sich vor, daß die N-Methyl-L-Glucosamin-Gruppe des Streptomycins das physiologische D-Glucosamin der Tuberkelbazillen im Sinne einer kompetitiven action verdrängt. Ein solcher Mechanismus ist nicht nur für die antibiologische Wirkung anzunehmen, sondern könnte darüber hinaus auch die toxischen Effekte an den Zellen des Organismus erklären.

Die Bedeutung der Glucosamin-Gruppe für die ototoxische Wirkung der Streptomycinsantibiotika geht auch aus den Untersuchungen Owadas hervor. Owada verglich die toxische Wirkung von Neomycin, Kanamycin, ihre Hydrolyseprodukte und deren N-Acetyl-Derivate. Es stellten sich dabei Unterschiede hinsichtlich der Allgemeintoxizität und des ototoxischen

Effektes heraus. Die LD₅₀ war besonders niedrig bei Neomycin, etwas höher bei Kanamycin. Von den einzelnen Komponenten des Neomycin- und Kanamycinmoleküls erwies sich die 2-Deoxystreptamlingruppe am toxischsten. Die allgemeine bzw. akute Toxizität kann demnach nicht auf eine einzelne Komponente des Neomycin- oder Kanamycinmoleküls zurückgeführt werden. Sie scheint vielmehr auf dem Gesamt-molekül zu beruhen.

Dagegen zeigte sich bei der Prüfung der ototoxischen Wirkung, daß 3-Glucosamin viel stärkere Hörschädigungen hervorruft als alle anderen untersuchten Substanzen. Es übertraf in dieser Hinsicht das 3-Acetyl-Glucosamin, Methyl-3-Glucosamin, 6-Glucosamin, aber auch Deoxystreptamin und sogar Kanamycin. Nur Neomycin war noch stärker ototoxisch als 3-Glucosamin. Owada schließt allerdings hieraus, daß auch die ototoxische Eigenschaft wahrscheinlich an das Gesamt-molekül der Streptomycesantibiotika gebunden ist. Zu der gleichen Ansicht kamen auch Aronson, Meyer und Brock (1964). Sie stellten ebenfalls fest, daß das SM-Molekül in seiner Gesamtheit ganz anders reagiert als seine Bausteine.

Neuere Vorstellungen und Erkenntnisse über den antibiotischen und toxischen Wirkungsmechanismus der Aminoglykosidantibiotika verdanken wir der Molekularbiologie. Während antibiotische und cytotatisch wirkende Substanzen, wie das Mitomycin, die DNS-Synthese oder das Actinomycin, die RNS-Synthese zu hemmen vermögen, haben die toxischen Streptomycesantibiotika im Gegensatz zu älteren Auffassungen offenbar auf die Nukleinsäuresynthese keinen Einfluß. Ihr Angriffspunkt ist vielmehr in der Proteinsynthese zu suchen, die durch Streptomycin unmittelbar und nicht erst über den Umweg einer Störung der DNS oder RNS blockiert wird.

Davies und Mitarbeiter (1964, 1965) und Gorini (1966) konnten im Experiment zeigen, daß sich Streptomycin an die eigentlichen Erweißproduktionsstätten, die Ribosomen, anlagert. Nach Cox, White und Flaks (1964) wird Streptomycin an die 30-S-Untereinheiten der Ribosomen gebunden, an der Stelle, wo auch die Messenger-RNS sitzt. Streptomycin vermag die Ribosomen so zu verändern, daß sie die im genetischen Code chemisch verschlüsselten Anweisungen für die Proteinsynthese, die ihnen von der Messenger-RNS übermittelt werden, falsch interpretieren.

Verwendet man z.B. Polyuridylsäure, ein synthetisches Polynukleotid, als Messenger-RNS, so wird normalerweise nur Phenylalanin eingebaut. Unter dem Einfluß des Streptomycins wird der Phenylalanineinbau verringert. An Stelle von Phenylalanin werden jetzt andere Aminosäuren, vor allem Isoleucin und Serin, aber auch Tyrosin und Leucin eingebaut. Streptomycin führt also zur Neubildung nicht funktioneller Proteine mit abnormaler Aminosäuresequenz. Es entstehen sog. Nonsense-Polypeptide.

Auf ähnliche Weise lassen sich auch die Wirkungen anderer Antibiotika wie Chloramphenicol, Paromycin und Tetracyclin erklären. Sie greifen ebenfalls in die Proteinsynthese ein, jedoch an einer anderen Stelle als die Streptomycesantibiotika. So hemmt Chloramphenicol z.B. an der 50-S-

Untereinheit der Ribosomen die Ablösung der bereits fertigen Peptidketten vom Ribosom und behindert dadurch die Proteinsynthese

Eine Möglichkeit einer Hemmung der Proteinsynthese konnte für Puromycin nachgewiesen werden. Seine nahe chemisch strukturelle Verwandtschaft zur Amino-acyl Transfer RNS deutet schon auf den Wirkungsmechanismus hin. Normalerweise wird im Verlauf der Proteinsynthese die Peptidkette von einem Transfer RNS-Molekül an das andere weitergereicht, wobei sie jedesmal um eine weitere Aminosäure zunimmt. In dem Augenblick aber, wo sich die Peptidkette irrtümlich an das ähnlich aussehende Puromycin anhängt, wird dieser Polymerisationsprozess unterbrochen und die unfertige Peptidkette löst sich vom Ribosom ab.

Dellweg (1966) nimmt an, daß alle bekannten Effekte des Streptomycins, wie die Schädigung der Zytoplasmamembran, Veränderungen der Zellwand und die Beeinflussung der oxydativen Phosphorylierung, Folgeerscheinungen dieser spezifischen Hemmung der Proteinsynthese und einer hierdurch hervorgerufenen Änderung der Permeabilitätschranke darstellen. Nicht in allen Ribosomen vermag Streptomycin die Proteinsynthese in gleicher Weise momentan zu hemmen. Die Wirkungen des Antibiotikums können sogar sehr unterschiedlich sein. Das gilt sowohl für die Bakterien als auch für die Körperzellen. Die Tatsache, daß einige Zellen sensibel, die anderen resistent sind, wird auf die unterschiedlichen Eigenschaften der jeweiligen Ribosomen zurückgeführt. Auch durch Mutationen können Stämme entstehen, die resistent sind oder sogar solche, die ein gewisses Streptomycinbedürfnis zeigen.

Eine weitere interessante Theorie über die Wirkungsweise des Streptomycins entwickelten Hurwitz und Rosano (1965). Sie konnten im Experiment zeigen, daß die tödliche Wirkung des Streptomycins und seine Fähigkeit, in die Zelle einzudringen, durch Chloramphenicol aufgehoben wird. Dieses gelang jedoch nicht mehr, wenn zuvor schon eine Streptomycinbehandlung mit niedrigen Dosen stattgefunden hatte. Die Verfasser schließen hieraus auf eine durch Streptomycin induzierte Permease, die es dem Antibiotikum erst ermöglichen soll, Permeabilitätschranken zu überwinden und in das Zellinnere zu gelangen. Das würde in der heutigen Terminologie bedeuten, daß unter Streptomycin zunächst eine de novo-Synthese einer spezifischen Messenger RNS, auch Transcription genannt, erfolgen muß, die in den Ribosomen die Synthese eines neuen spezifischen Proteins, einer Permease, eine sog. Translation, veranlaßt. Durch Chloramphenicol soll die Synthese der spezifischen Permease in den Ribosomen gehemmt und dadurch die Streptomycineinwirkung aufgehoben werden. Der entgiftende Effekt des Chloramphenicols wird daher unwirksam, wenn schon vorher Streptomycin gegeben wurde und die Synthese der Permease bereits erfolgt ist.

In jüngster Zeit berichteten Holz, Stange und Terravania über aufseherregende Erfolge mit Oxothlin, das die Giftwirkung des SM und aller anderen Oligosaccharidantibiotika aufheben soll. Oxothlin ist die Ware

bezeichnung für ein Kombinationspräparat aus Oxydationsprodukten des Oleum Terebinthinæ und Terpinum hydratum, das klinisch als Expectorans Anwendung findet, aber auch als Lösungsmittel für Antibiotika empfohlen wird. Bis heute fehlt es an fundierten Vorstellungen über den Wirkungsmechanismus des Oxothins, insbesondere auch hinsichtlich der entgiftenden Eigenschaft.

Die große Zahl der zur Entgiftung empfohlenen Substanzen, von denen die meisten einer genaueren Nachprüfung nicht standhielten, beweist, mit welcher Vorsicht eine Entgiftung zu bewerten ist. Die wichtigsten Substanzen, die z. Zt. im Mittelpunkt der Diskussion stehen, wie das Oxothin und die verschiedenen Pantothenatsalze der Aminoglykosidantibiotika wurden mit in unsere Versuchsreihe aufgenommen und im Rahmen unsere Fragestellung auf ihre angeblich entgiftende Wirkung hin untersucht.

C NEUE ASPEKTE UND EXPERIMENTELLE UNTERSUCHUNGEN

I Die Organspezifität der Streptomycinvergiftung und ihre Abgrenzung gegenüber unspezifischen Ototoxikosen

Die spezifischen Ototoxikosen stellen eine Sonderform der Innenohrintoxikation dar. Daß der N. statoacusticus häufiger als andere Hirnnerven durch Gifte verschiedenster Art geschädigt wird, stellte Taylor bereits im Jahre 1937 fest. Von den zahlreichen Substanzen, die eine Innenohrschädigung hervorrufen können, seien hier nur das Arsenik, Oleum chenopodii, Jodkallium, Chloroform, Jodoform, Alkaloide, verschiedene Gase wie Kohlenmonoxyd, Chlor, Phosgen, Cyan, Acetylen, Schwefelwasserstoff u. a. Schwermetalle (Ag, Hg und Pb) oder Nitrobenzol, Anilin und Phosphor und, wie vielfach angenommen wird, auch Alkohol und Nikotin erwähnt.

Größere praktische Bedeutung erlangten die Hörverluste nach Chinin, vor allem bei der Bekämpfung der Malaria, die eine langer dauernde und höher dosierte Behandlung erforderte. Aber selbst unter so harmlos erscheinenden Medikamenten wie Aspirin und anderen Salicylsäurepräparaten stellen sich Hörschädigungen ein, die allerdings i. G. zum Chinin weniger stark ausgeprägt und vor allem stets reversibel sind (Wittmann 1903, Pohlmann und Kranz, 1922, Covell 1936, Falbe Hansen 1941, Jäger und Altway 1946, Graham und Parker 1948, Waltener 1950, McCabe und Dev 1965, Myers und Bernstein, 1965).

Covell verglich an Kaninchen, Meerschweinchen und Mäusen die Veränderungen, die durch Chinin und Salicylate hervorgerufen werden. Die Substanzen wiesen ein unterschiedliches Schädigungsbild auf: Salicylsäure scheint gegenüber Chinin bevorzugt die Zellen des Ganglion cochleare zu treffen.

Auch der klinische Verlauf der Innenohrintoxikation ist bei beiden Substanzen verschieden. Hörschaden durch Chinin sind in der Regel nicht mehr rückbildungsfähig. Sie können sogar nach Absetzen des Medikaments noch weiter fortschreiten. Dagegen bilden sich die Ohrgeräusche, Schwindelercheinungen und die Schwerhörigkeit nach Aspirin, die selten 40 dB überschreitet, innerhalb von 72 Stunden nach Absetzen des Präparates vollständig zurück. Die Salicylototoxikose soll nach Myers und Bernstein so risikolos sein, daß sie ohne Bedenken zur Erzeugung experimenteller Hörstörungen beim Menschen angewandt werden kann.

Kapur (1966) teilte allerdings einen Fall mit, bei dem im Rahmen eines fieberhaften Infektes bereits nach 3 Aspirin-Tabletten eine Taubheit eintrat. Er vermutet, daß hier eine besondere Überempfindlichkeit vorliegen hat.

Auf eine Überempfindlichkeit gegenüber Aspirin wies Taylor schon im Jahre 1937 hin. Eine permanente Ertaubung durch Aspirin stellt nach seiner Meinung eine Ausnahme dar und ist nur bei einer sog. Idiosynkrasie gegen dieses Medikament zu erwarten.

Diese vereinzeltten Beobachtungen widersprechen den klinischen und experimentellen Befunden Myers, Bernsteins und der anderen Autoren. Die Entscheidung, ob Salicylate ursächlich für eine Hörstörung in Betracht kommen, ist in einzelnen Beobachtungsfällen sehr schwierig und kann höchstens mit einer gewissen Wahrscheinlichkeit getroffen werden. Es ist stets dabei zu bedenken, daß plötzliche Ertaubungen unter der Bezeichnung „akuter Hörsturz“ oder „sudden deafness“ ein bekanntes und nicht einmal seltenes Krankheitsbild darstellen, das in den meisten Fällen ohne jede erkennbare Ursache auftritt. Im allgemeinen werden hierfür Durchblutungsstörungen verschiedenster Art oder Virusinfekte angeschuldigt (Verell, 1963). In Anbetracht der außerordentlich weiten Verbreitung der Salicylatanwendung könnte es sich deshalb um zufällig zeitlich zusammenfallende Ereignisse handeln, die in keiner ursächlichen Beziehung zueinander stehen. Diese Möglichkeit ist auch bei dem von Kapur mitgeteilten Fall zu berücksichtigen. Allein durch den fieberhaften Infekt könnte hier die Schwerhörigkeit hervorgerufen worden sein.

Erst recht ist die vor kurzem von Jarvis (1966) beschriebene einseitige Ertaubung nach Aspirin mit Zurückhaltung zu beurteilen, nicht nur weil toxische Schädigungen in der Regel beide Ohren treffen. Vor allem ist hier auffällig, daß ausgerechnet die Seite ertaubte, auf der die ausgedehnte phlegmonöse Entzündung der einen Gesichtshälfte bestand, derentwegen letztlich die Aspirinbehandlung erfolgte. Auch hier spricht vieles dafür, daß die Primärerkrankung die Ursache der Hörstörung ist.

Von diesen wenigen und umstrittenen Ausnahmen abgesehen, kann für alle oben aufgeführten ototoxischen Substanzen das gleiche Wirkungsprinzip angenommen werden. Ihre toxische Wirkung ist aus folgenden Gründen als unspezifisch zu bezeichnen:

1. weil eine Schädigung nur bei extrem hoher Dosierung auftritt, also bereits Ausdruck einer Überdosierung ist, und
2. weil sie nicht ausschließlich auf das Innenohr oder einige wenige Organe beschränkt und damit nicht organspezifisch ist.

Die Innenohrschädigung stellt hier lediglich ein Symptom eines komplexen Vergiftungsbildes unter vielen anderen dar. Die Schwerhörigkeit steht allerdings deswegen häufig im Vordergrund und erregt besondere Aufmerksamkeit, weil sie meistens irreparabel ist und als ein besonders auffälliges Symptom bestehen bleibt, während die anderen toxischen Erscheinungen längst abgeklungen sind.

Im Gegensatz hierzu zeichnen sich die Streptomycesantibiotika der Oligosaccharidgruppe dadurch aus, daß sie schon in sog. therapeutischen Dosen zu Schädigungen führen, die bemerkenswerterweise ausschließlich das

(Bugge, Pilling, Bornstein und Hirsfeld, 1946 Marshall 1948 Levin, Carr und Hellman, 1948 Rake, Pansy Jambor und Donovick, 1948 Cronk und Neumann, 1959)

Ihre charakteristischen Permeationseigenschaften erklären, warum sie nicht gleichmäßig im Organismus verteilt sind, sondern in den einzelnen Organen in sehr unterschiedlichen Konzentrationen vorkommen.

Aufschluß über die Verteilung und das Konzentrationszeitverhalten der basischen Streptomycosan Antibiotika geben die Untersuchungen André, die mit tritiummarkiertem DSM durchgeführt wurden. Nach intravenöser Injektion dieser Substanz stellte sich zunächst für eine kurze Zeit ein hoher Blutspiegel ein. Wenig später ließen sich vor allem in der Lunge, im Bindegewebe im Knorpel und in der Niere hohe DSM Konzentrationen nachweisen, die etwa die Höhe des Blutspiegels erreichten. Nur das Gehirn fiel durch einen besonders niedrigen DSM-Gehalt auf, der lediglich 16% der Blutkonzentration ausmachte. Der DSM-Gehalt des Innenohres wurde bei der von André, wahrscheinlich wegen der technischen Schwierigkeiten, nicht untersucht. Bereits nach 320 Minuten post inject. war DSM, wie Tursten André zeigen konnte, aus dem Blut und aus den meisten Organen wieder weitgehend eliminiert. Aber im Knorpelgewebe und in den Ausscheidungsvorganen, der Niere, der Leber und den Gallenwegen sowie im Darm, fanden sich zu diesem Zeitpunkt immer noch mittlere DSM Konzentrationen.

Die Aminoglykosidantibiotika werden praktisch unverändert zum überwiegenden Teil durch die Nieren aber auch über die Leber und Galle via Darm ausgeschieden. Wie Clearanceuntersuchungen zeigten, erfolgt die renale Ausscheidung ausschließlich durch glomeruläre Filtration und nicht durch aktive Sekretionsleistungen der Tubulazellen (Edison, Jelinek und Boxer 1949). Wie oben bereits erwähnt wurde findet auch praktisch keine tubuläre Rückresorption dieser Substanzen statt.

Stæmmer und Drukowiak (1961) konnten allerdings eine Speicherung der toxischen Streptomycosan Antibiotika in den Tubulasepithelien feststellen. Die Anreicherung in den Tubulazellen war bei den einzelnen Antibiotika unterschiedlich stark ausgeprägt. Interessanterweise lagerten sich die stärksten oto- und nephrotoxischen Substanzen auch am meisten in den Tubuli ab. So fand man hier vor allem hohe Konzentrationen von Neomycin, auch Kanamycin, weniger dagegen DSM und am wenigsten SM.

Man muß sich fragen, worauf diese unterschiedliche Anreicherung zurückzuführen ist. Ist es das charakteristische Permeationsverhalten, insbesondere die schlechte Resorbierbarkeit dieser Substanzen, die zu den Ablagerungen und schließlich zur toxischen Schädigung führt. Oder sind die Ablagerungen nicht die Ursache sondern nur eine Folge der toxischen Wirkung? Die Vermutung liegt zwar nahe, daß durch die Speicherung der toxischen Antibiotika in den Tubulazellen eine Störung und Schädigung hervorgerufen wird. Umgekehrt könnte man sich aber auch vorstellen, daß die Streptomycosan Antibiotika erst sekundär in den toxisch geschädigten Zel-

Innenohr und die Niere betreffen. Nur ihre toxische Wirkung kann deshalb als organspezifisch bezeichnet werden. Im folgenden soll versucht werden, die Ursache der Organspezifität zu erklären.

II Die Permeationseigenschaften und die Verteilung der Aminoglykosidantibiotika im Organismus

Bei den bisher betrachteten toxikologischen Untersuchungen standen vor allem zwei Eigenschaften der stark basischen Charakter und die Zuckerkomponente des Streptomycinmoleküls im Vordergrund. Darüberhinaus zeichnen sich die toxischen Streptomycinantibiotika gegenüber den anderen antibiotischen Substanzen noch durch ein weiteres gemeinsames Merkmal aus, nämlich ihr besonders schlechtes Permeationsvermögen. Diesem eigentümlichen Verhalten der Oligosaccharidantibiotika wurde bis heute keine Beachtung geschenkt. Für die Entstehung der organspezifischen Vergiftungen scheint ihm jedoch eine besondere Bedeutung zuzukommen.

Es ist auffällig, daß alle toxischen Antibiotika sowohl die der Aminoglykosidgruppe als auch die Polymyxine mit Polypeptidstruktur nicht resorbiert werden können. Sie finden sich überwiegend im extrazellulären Raum. Nach Robson und Sullivan (1963) vermag Streptomycin und das gleiche muß auch für die verwandten Substanzen dieser Gruppe angenommen werden, nur sehr schlecht in die Zelle einzudringen. So ist auch zu verstehen, warum diese Stoffe von den Zellen nicht aktiv sezerniert werden können. Im Blut fand Torsten André (1956) tritiummarkiertes DSM nur im Plasma, nicht aber in den zellulären Elementen, den roten und weißen Blutkörperchen. Auch die Epithellen der Darmmucosa und der Nierentubuli sind offenbar nicht in der Lage, diese unphysiologischen Oligosaccharide aktiv aufzunehmen, zu resorbieren. Für den Transport der basischen Antibiotika innerhalb des Organismus kommen daher praktisch ausschließlich passive Vorgänge wie Diffusion oder Filtration in Betracht. Das Verhalten der Oligosaccharidantibiotika erinnert in dieser Hinsicht sehr an Substanzen wie Inulin oder Mannitol, die auf Grund dieser besonderen Eigenschaften zur Bestimmung des Extrazellulärraumes oder bei Clearanceuntersuchungen zur Feststellung der Filtrationsgröße Anwendung finden. Auf Inulin soll deswegen an anderer Stelle noch näher eingegangen werden.

Die Möglichkeit, auf passivem Wege in die Zelle zu diffundieren, scheint zumindest für das Streptomycinmolekül nur eine untergeordnete und im allgemeinen zu vernachlässigende Rolle zu spielen. Nur bei besonders hohen Antibiotikakonzentrationen wie sie z. B. in den Nierentubuli anzutreffen sind, scheinen, durch das steile Konzentrationsgefälle begünstigt, größere Mengen der toxischen Substanzen in die oberflächlichen Epithelschichten eindringen zu können.

Alle Antibiotika der Aminoglykosidgruppe verhalten sich hinsichtlich ihrer Resorption, Verteilung und Ausscheidung grundsätzlich ähnlich.

spezifisch hohen Antibiotikagehalt der Innenohrflüssigkeiten zurückzuführen ist.

Höhere Konzentrationen der Aminoglykosidantibiotika finden sich, wie bereits erwähnt wurde, nicht nur in der Niere sondern auch im Darm. Der Resorptionsprozeß des Darmes weist bemerkenswerte Analogien zu den Vorgängen in den Nierentubuli auf (Stupp, 1960; Rummel und Stupp, 1960 und 1962). Der Darm vermag ebenfalls die toxischen Antibiotika nicht zu resorbieren. Deshalb eignen sich die Streptomycesubstanzen auch besonders gut zur präoperativen Darmsterilisation. Bei den hier angewandten extrem hohen Dosen konnte allerdings beobachtet werden, daß unter diesen Bedingungen etwa 3% vom Darm aufgenommen werden und in den Organismus gelangen. So ist es zu erklären, daß auch bei enteraler Applikation u. U. Intoxikationserscheinungen vorkommen können.

Ähnlich wie bei der Harnkonzentration in den Nierentubuli erfahren die toxischen Antibiotika im Verlaufe der enteralen Resorption eine Anreicherung. Während der größte Teil des Darminhaltes der Resorption unterliegt, bleiben die nicht resorbierbaren Antibiotika im Darm zurück und erreichen hier höhere Konzentrationen.

Nicht nur in funktioneller Hinsicht, sondern auch im elektronenmikroskopischen Bild, lassen sich übereinstimmende Merkmale zwischen den Epithelien des Darmes und des Nierentubulus erkennen. Enge morphologische und funktionelle Beziehungen bestehen nach Rauch (1961) aber auch zwischen den Nierenepithelien und dem Epithel der *Sirra vascularis* des Innenohres, einer Epithelschicht, die durch eine besonders starke Vascularisation und intensiven Stoffwechsel auffällt. Sie kleidet die laterale Wand des Endolymphraumes aus und wird als Resorptionsort für die Innenohrflüssigkeiten angesehen (Abb. 1).

Dem Darm kommt hier insofern eine Bedeutung zu, da er für unsere Untersuchungen zur Klärung des Schädigungsweges die weitaus günstig

Abb. 1 Anatomie des Innenohres.

len abgelagert werden und das Ausmaß dieser Ablagerung nur Ausdruck der Stärke der Schädigung ist

III Untersuchungen zur Frage des Intoxikationsweges

Auf welchem Wege Kanamycin in die Tubuluszellen gelangt, ob durch Rückresorption aus dem Tubulolumen oder aus entgegengesetzter Richtung durch direkte Aufnahme aus dem Blutkreislauf, wagt Mückler (1961) nicht zu entscheiden. Die Streptomycineantibiotika erreichen, da sie nicht rückresorbiert werden können, in den Nierentubuli im Gefolge der Harnkonzentrierung die weitaus höchsten Konzentrationen, die überhaupt im Organismus feststellbar sind. Messungen des Kanamycingehaltes im Harn ergaben Werte, die den höchsten Blutspiegel noch um mehr als das 150-fache übertreffen (Stupp *et al.*, 1965). In Anbetracht des viel niedrigeren Blutspiegels erscheint eine vom Blut ausgehende Schädigung wenig wahrscheinlich. Wäre dies der Fall, so müßte man erwarten, daß die Blutkonzentration annähernd überall gleich hoch ist, daß andere Zellen genauso von der Giftwirkung in Mitleidenschaft gezogen werden. Es wäre dann nicht einzusehen, warum ausgerechnet die Tubulusepithelien geschädigt werden. Die Tatsache, daß nur die oberflächlichen Epithelschichten betroffen sind, scheint für die Annahme zu sprechen, daß die Schädigung vom Tubulolumen aus erfolgt und wahrscheinlich auf die extrem hohe Konzentration im Primärharn zurückzuführen ist.

Die Frage des Schädigungsweges ist für das Verständnis des toxischen Wirkungsmechanismus von grundlegender Bedeutung. Erfolgt nämlich die Schädigung der Tubuli vom Blut aus, so würde das bedeuten, daß die Tubulusepithelien im Vergleich mit anderen Zellen, die der gleichen Blutkonzentration ausgesetzt sind, besonders empfindlich sind. Für den Fall aber, daß die toxischen Substanzen unmittelbar vom Tubulolumen aus auf die Tubulusepithelien einwirken, müßte die Schädigung als Folge der hohen Antibiotikakonzentration im Harn aufgefaßt werden. Das ließe aber mit anderen Worten, die Intoxikation beruht nicht auf einer organspezifischen Sensibilität der Niere, sondern in erster Linie auf der spezifisch hohen Antibiotikakonzentration.

Der Weg, auf dem die toxischen Antibiotika den Schädigungsort erreichen, verdient deswegen eine eingehendere Betrachtung, weil für das Innenohr sehr ähnliche Verhältnisse anzunehmen sind. Auch hier stehen wir vor der gleichen Frage: erfolgt die Schädigung von der Blutseite her, d. h., zeichnet sich das Innenohr durch eine spezifische Empfindlichkeit aus, wie heute noch allgemein angenommen wird, oder findet sie von den Innenohrräumen und den Innenohrflüssigkeiten aus statt. Im letzteren Fall müßte daran gedacht werden, ob nicht im Innenohr ähnlich wie in den Nierentubuli besonders hohe Antibiotikakonzentrationen vorkommen. Hiermit würde auch die Frage entschieden, ob die sog. spezifische Ototoxikose auf einer spezifischen Sensibilität des Innenohres beruht oder ob sie auf einem

spezifisch hohen Antibiotikagehalt der Innenohrflüssigkeiten zurückzuführen ist

Höhere Konzentrationen der Aminoglykosidantibiotika finden sich, wie bereits erwähnt wurde, nicht nur in der Niere sondern auch im Darm. Der Resorptionsprozeß des Darmes weist bemerkenswerte Analogien zu den Vorgängen in den Nierentubuli auf (Stupp, 1960 Rummel und Stupp, 1960 und 1962). Der Darm vermag ebenfalls die toxischen Antibiotika nicht zu resorbieren. Deshalb eignen sich die Streptomycessubstanzen auch besonders gut zur präoperativen Darmsterilisation. Bei den hier angewandten extrem hohen Dosen konnte allerdings beobachtet werden, daß unter diesen Bedingungen etwa 3% vom Darm aufgenommen werden und in den Organismus gelangen. So ist es zu erklären, daß auch bei enteraler Applikation u. U. Intoxikationserscheinungen vorkommen können.

Ähnlich wie bei der Harnkonzentration in den Nierentubuli erfahren die toxischen Antibiotika im Verlaufe der enteralen Resorption eine Anreicherung. Während der größte Teil des Darminhaltes der Resorption unterliegt bleiben die nicht resorbierbaren Antibiotika im Darm zurück und erreichen hier höhere Konzentrationen.

Nicht nur in funktioneller Hinsicht, sondern auch im elektronenmikroskopischen Bild, lassen sich übereinstimmende Merkmale zwischen den Epithellen des Darmes und des Nierentubulus erkennen. Enge morphologische und funktionelle Beziehungen bestehen nach Ranch (1961) aber auch zwischen den Nierenepithellen und dem Epithel der Stria vascularis des Innenohres, einer Epithelschicht, die durch eine besonders starke Vascularisation und intensiven Stoffwechsel auffällt. Sie kleidet die laterale Wand des Endolymphraumes aus und wird als Resorptionssort für die Innenohrflüssigkeiten angesehen (Abb. 1)

Dem Darm kommt hier insofern eine Bedeutung zu da er für unsere Untersuchungen zur Klärung des Schädigungsweges die weitaus günstig-

Abb. 1 Anatomie des Innenohres.

sten Versuchsbedingungen bietet. Er diente gleichsam als Modell zum Studium des Intoxikationsmechanismus und insbesondere des Schädigungsweges von dem man annehmen darf, daß er wahrscheinlich in den Neren-tubuli und Innenohrräumen ähnlich verläuft, dessen Untersuchung hier aber aus verständlichen methodischen Gründen viel schwieriger ist. Ziel dieser Untersuchungen war es vor allem festzustellen, ob Kanamycin trotz seiner bekannten schlechten Resorbierbarkeit in der Lage ist, vom Darm lumen aus, also unter Umgehung des Blutweges, auf die Darmepithelien einzuwirken und diese unter Umständen zu schädigen. Zu diesem Zweck wurden Dünndarmabschnitte am lebenden narkotisierten Meerschweinchen mit Kanamycinsulfatlösungen und in benachbarten Abschnitten zum Vergleich mit Ringerlösung gefüllt und dann verschlossen.

Methodik

Als Versuchstiere dienten Meerschweinchen mit einem durchschnittlichen Gewicht von 250 g. Die Tiere erhielten als Basisnarkotikum 10 mg Urethan/kg intraperitoneal und zusätzlich eine Ätherinhalationsnarkose. Nach Eröffnung des Abdomens wurden 2 gleich lange Jejunumabschnitte freigelegt und unter Erhaltung der Durchblutung die Darmlumen eröffnet. Zunächst wurde der Darm zur Reinigung mit Ringerlösung durchgespült und anschließend in einen Darmabschnitt eine isotonische 15%ige Kanamycinsulfatlösung mit einem pH von 6,8 und in den anderen ein gleich großes Volumen Ringerlösung gefüllt. Danach wurde das Darmlumen durch eine Unterbindung abgeschlossen, die Darmstücke wieder in die Bauchhöhle zurückverlagert und die Bauchdecke verschlossen. Der Darminhalt wurde nach 14 Stunden Versuchsdauer gewogen und das Gewebe zur histologischen Untersuchung in Formalinlösung fixiert, eingebettet und nach Heidenhain mit Hamatoxylin-Eosin gefärbt.

Ergebnisse

In dem Darmabschnitt, der Kanamycin enthielt, fiel verglichen mit dem benachbarten Kontrolldarmsstück zunächst eine ausgeprägte Hyperämie auf. Der Darm erschien hochrot bis leicht bläulich verfärbt. Die gleiche Beobachtung machte Müsebeck (1962) auch am Innenohr nach SM-Intoxikationen.

Im weiteren Verlauf zeigte es sich, daß die Ringerlösung wesentlich schneller resorbiert wird. Der Resorptionsprozeß war unter Kanamycin offensichtlich gehemmt. Am Ende des Versuches war der Kanamycin enthaltende Darm fast genauso voll wie zu Beginn, während der Kontrolldarm praktisch leer war. Auf die Bestimmung des Kanamycin Gehaltes wurde bei diesen Untersuchungen, die lediglich orientierenden Charakter haben sollen, verzichtet, zumal die schlechte Resorbierbarkeit des Kanamycins allgemein bekannt ist.

Uns interessieren vor allem die histologischen Veränderungen an den

Abb. 2. (a) Darmepithelien unter Kanamycin, (b) Kontrolldarm (Ringerlösung)

Darmepithelien, wie sie auf Abb. 2a und Abb. 3a und zum Vergleich in den Kontrolldarmabschnitten Abb. 2b und Abb. 3b zu erkennen sind.

Hier zeigt sich ein sehr ähnliches Schädigungsbild, wie es bereits von den Tubuluszellen und vom Innenohr bekannt ist und übereinstimmend von zahlreichen Autoren beschrieben wurde. Die Mucosazellen waren unter Kanamycin deutlich vergrößert, aufgetrieben und ihre Zellgrenzen nicht mehr zu erkennen. In den Zellen fanden sich große Vacuolen. Am auffälligsten war die Vergrößerung und Schwellung der Zellkerne. Sie fielen außerdem durch eine intensivere Färbung und eine unregelmäßige Form auf. Ein Nucleolus ließ sich nicht mehr feststellen. Demgegenüber konnten am Kontrolldarm keine pathologischen Veränderungen festgestellt werden. Die Zellkerne waren hier viel kleiner, rundlich bis oval. Sie besaßen in ihrer

Abb. 3. (a) Darmepithelien unter Kanamycin mit großen, intrazellulären Vacuolen, (b) Kontrolldarm (Ringerlösung)

sten Versuchsbedingungen bietet. Er diente gleichsam als Modell zum Studium des Intoxikationsmechanismus und insbesondere des Schädigungsweges, von dem man annehmen darf, daß er wahrscheinlich in den Nierentubuli und Innenohrräumen ähnlich verläuft. Dessen Untersuchung hier aber aus verständlichen methodischen Gründen viel schwieriger ist. Ziel dieser Untersuchungen war es vor allem festzustellen, ob Kanamycin trotz seiner bekannten schlechten Resorbierbarkeit in der Lage ist, vom Darmlumen aus, also unter Umgehung des Blutweges, auf die Darmepithellen einzuwirken und diese unter Umständen zu schädigen. Zu diesem Zweck wurden Dünndarmabschnitte am lebenden narkotisierten Meerschweinchen mit Kanamycinsulfatlösungen und in benachbarten Abschnitten zum Vergleich mit Ringerlösung gefüllt und dann verschlossen.

Methodik

Als Versuchstiere dienten Meerschweinchen mit einem durchschnittlichen Gewicht von 250 g. Die Tiere erhielten als Basisnarkotikum 10 mg Urethan/kg intraperitoneal und zusätzlich eine Ätherinhalationsnarkose. Nach Eröffnung des Abdomens wurden 2 gleich lange Jejunumabschnitte freigelegt und unter Erhaltung der Durchblutung die Darmlumen eröffnet. Zunächst wurde der Darm zur Reinigung mit Ringerlösung durchgespült und anschließend in einen Darmabschnitt eine isotonische 15%ige Kanamycinsulfatlösung mit einem pH von 6,8 und in den anderen ein gleich großes Volumen Ringerlösung gefüllt. Danach wurde das Darmlumen durch eine Unterbindung abgeschlossen, die Darmfläche wieder in die Bauchhöhle zurückverlagert und die Bauchdecke verschlossen. Der Darminhalt wurde nach 14 Stunden Versuchsdauer gewogen und das Gewebe zur histologischen Untersuchung in Formalinlösung fixiert, eingebettet und nach Heidenhain mit Hämatoxylin-Eosin gefärbt.

Ergebnisse

In dem Darmabschnitt der Kanamycin enthielt fiel verglichen mit dem benachbarten Kontrolldarmstück zunächst eine ausgeprägte Hyperämie auf. Der Darm erschien hochrot bis leicht bläulich verfärbt. Die gleiche Beobachtung machte Müsebeck (1962) auch am Innenohr nach SM-Intoxikationen.

Im weiteren Verlauf zeigte es sich, daß die Ringerlösung wesentlich schneller resorbiert wird. Der Resorptionsprozeß war unter Kanamycin offensichtlich gehemmt. Am Ende des Versuches war der Kanamycin enthaltende Darm fast genauso voll wie zu Beginn, während der Kontrolldarm praktisch leer war. Auf die Bestimmung des Kanamycingehaltes wurde bei diesen Untersuchungen der lediglich orientierende Charakter haben sollen verzichtet, zumal die schlechte Resorbierbarkeit des Kanamycins allgemein bekannt ist.

Uns interessieren vor allem die histologischen Veränderungen an den

Mitte einen Nucleolus und wiesen eine scharfe Begrenzung zum Zytoplasma auf

Aus diesen Untersuchungen am Darm können folgende Schlüsse gezogen werden

- 1 Kanamycin und wahrscheinlich auch alle anderen Streptomycosantibiotika rufen eine allgemeine Störung der Resorptionstätigkeit hervor
- 2 Die Schädigung der Epithellen des Darmes erfolgt vom Lumen d. h. von der Mucosaseite aus und nicht auf dem Blutweg. Das bedeutet
- 3 Das Antibiotikum kann, obwohl es nicht resorbierbar ist dennoch vom Darmlumen aus in die oberste Zellschicht eindringen und diese schädigen
- 4 Die toxischen Streptomycosantibiotika können nicht nur das Innenohr und die Niere sondern auch andere Organe wie z. B. den Darm, schädigen Voraussetzung ist nur daß diese einer entsprechend hohen Kanamycinkonzentration ausgesetzt werden Mit anderen Worten die toxische Wirkung scheint nicht in erster Linie auf einer spezifischen Sensibilität einzelner Organe zu beruhen, sondern von der Konzentration abhängig zu sein
- 5 Die große Ähnlichkeit des Schädigungsbildes an den Epithellen des Darmes, der Niere und des Innenohres spricht dafür daß die Wirkungsweise der toxischen Stoffe überall die gleiche ist

Damit soll jedoch nicht gesagt sein, daß alle Zellen des Organismus die gleiche Empfindlichkeit besitzen und die Konzentration die alleinige Ursache für die Schädigung darstellt Sicher wird es auch innerhalb der Organe das beweisen zahlreiche morphologische Untersuchungen am Innenohr (Kohonen, 1965 Koide *et al.*, 1966 Spoendlin 1966 u. a.) noch erhebliche Empfindlichkeitsunterschiede der einzelnen Zelltypen geben genauso wie man bei den bakteriologischen Resistenzbestimmungen große Unterschiede in der Sensibilität der einzelnen Erreger feststellen kann Mit zunehmender Antibiotikakonzentration wird zwar der Kreis der empfindlichen Keime bzw. Zellen größer So wird z. B. eine Sinnes- oder Nervenzelle früher geschädigt werden als z. B. eine Bindegewebszelle Genauso wie im Innenohr gibt es in anderen Organen ebenfalls mehr oder weniger empfindliche Zellen Wir haben keine Veranlassung anzunehmen die Epithellen oder neuronalen Elemente des Innenohres seien empfindlicher wie häufig behauptet wird als gleichartige Zellelemente anderer Organe

In den Befunden am Darm sehen wir eine Bestätigung für unsere Annahme daß wahrscheinlich auch für die Nierenschädigungen die hohe Antibiotikakonzentration im Harn und nicht der Antibiotikaspiegel des Blutes verantwortlich zu machen ist Die Tatsache das die toxischen Substanzen, insbesondere in den resorptiv tätigen Organen z. B. in der Niere oder dem Darm, angereichert werden, veranlaßt uns nachzuforschen, ob nicht auch im Innenohr wo ebenfalls ein Resorptionsprozeß stattfindet auf ähnliche Weise eine Kumulation erfolgt

Über den Streptomycingehalt des Innenohres war wenn man von einigen Mitteilungen absteht, bis vor kurzem nur wenig bekannt. In der Literatur findet sich lediglich eine Mitteilung von Baroni, Zansucchi und Masera (1950). Sie verabreichten Tauben 100 mg SM Sulfat intramuskulär und verglichen 10 min. nach der Injektion den SM-Gehalt des Blutes und der Innenohrlymphe, die aus den Bogengängen entnommen wurde. Die Bestimmung der SM Konzentration in den Proben erfolgte auf mikrobiologischem Wege an einem Staphylokokkteststamm. Im Blut war kein Streptomycin nachweisbar wohl aber in der Lymphe. Man schloß hieraus, daß die Streptomycinkonzentration in der Lymphe höher sein muß als im Blut. Genauere Untersuchungen über das Verhalten der verschiedenen Aminoglykosidantibiotika im Organismus und vor allem im Innenohr wurden erst in jüngster Zeit gleichzeitig von mehreren Untersuchern durchgeführt (Muravelskaya, 1965; Stupp und Rauch, 1965; Vabree, 1965; Voldrich, 1965).

Die Ursache, warum derartige Untersuchungen erst jetzt vorgenommen wurden, ist in erster Linie in den erheblichen methodischen Schwierigkeiten, insbesondere der Endolymphgewinnung zu suchen.

IV Vergleich der Antibiotikaspiegel im Blutserum, in den Innenohrflüssigkeiten und anderen Organen

318 Meerschweinchen mit einem durchschnittlichen Gewicht von 250 g erhielten eine einmalige subkutane Injektion eines Antibiotikums entweder aus der Oligosaccharidgruppe oder Polymyxin E (Colistin²) Tetracyclin und Penicillin G. Anschließend wurden die Antibiotikakonzentrationen über einen Zeitraum von 25 Stunden in der Peri- und Endolymph des Innenohres und zum Vergleich im Blutserum, Herzmuskel, in der Leber im Großhirn sowie im vestibulären Kerngebiet des Hirnstammes bestimmt. Die Messungen erfolgten 10 Minuten, 1/2, 1 Stunde, zwei, fünf zwölf acht zehn und fünfundzwanzig Stunden nach einer einmaligen Injektion. Für jede einzelne Bestimmung mußte jeweils ein Tier geopfert werden. Die folgende Aufstellung gibt die untersuchten Substanzen und ihre Dosierungen an. Alle Gewichte beziehen sich stets auf die Antibiotika Base

Antibiotikum	Dosierung
1. Kanamycin-Sulfat	250, 50, 25 und 15 mg/kg
2. Kanamycin-Monopentathemat	250 mg/kg
3. Kanamycin-Dipentathemat	250 mg/kg
4. Kanamycin-Tripentathemat	250 mg/kg
5. Streptomycin-Sulfat	250 mg/kg
6. Dihydrostreptomycin-Sulfat	250 mg/kg
7. Neomycin-Sulfat	100 mg/kg und 25 mg/kg
8. Colistin (Polymyxin E) als Methanesulfonate-Na	1 ME E = 25 mg/kg
9. Tetracyclin-HCl	100 mg/kg
10. Penicillin G	400 000 E = 250 mg/kg

Methode

Zur Gewinnung der Endo- und Perilymphflüssigkeit mußten die Meeresschweinchen dekapitiert werden. Anschließend wurde die Bulla in wenigen Sekunden freipräpariert, weil eröffnet, damit die Cochlea gut zugänglich wird und sofort in flüssigem Stickstoff eingefroren. In einer Tiefkühlkammer bei -20° erfolgte dann unter einem Operationsmikroskop (Zeiss) die Entfernung der knöchernen Kapsel der Schnecke mit Hilfe einer Fräse. Nach der von Rauch beschriebenen Technik (s. Biochemie des Innenohres, Thieme Verlag) läßt sich dann die Perilymphe der Scala vestibuli und tympani sowie die Endolympe des Ductus cochlearis in den einzelnen Windungen der Schnecke in kleinen Bruchstücken voneinander trennen. Die aus einer Schnecke gewonnene Endolymphmenge betrug maximal 12 μ l. Da zur bakteriologischen Messung des Antibiotikagehaltes bzw. genauer gesagt der antibakteriellen Aktivität relativ große Lymphmengen erforderlich waren, mußten stets die Endolymphen von 3–6 Tieren zusammengekommen und ausgewertet werden. Evtl. Blutbeimischungen ließen sich durch eine photometrische Hb-Bestimmung feststellen und berechnen.

Aus verständlichen methodischen Gründen konnte nicht in allen Fällen die Endolymphpräparation durchgeführt werden. Die Perilymphgewinnung bereitete demgegenüber keine besonderen Schwierigkeiten. Sie konnte am lebenden Tier in Urethan-Narkose durchgeführt werden. Die Bulla wurde hierbei freipräpariert, eröffnet und mit einer Nadel ein kleines Bohrloch zur Scala vestibuli der unteren Schneckenwindung angebracht. Aus dieser Öffnung konnte mit einer dünnen ausgezogenen Glaskapillare durch Adhäsion Perilymphe aus der Scala vestibuli abgezogen werden. Die Lymphflüssigkeit wurde in kleinen gut verschließbaren Polyethylenpipetten

Abb. 4. Blutspiegel nach 100 mg Kanamycin i. m. 250 mg Kanamycin i. m. 1 g/kg bezogen auf die Kanamycin-Basis

behältern gesammelt und die Lymphmenge auf der Mikrowaage bestimmt. Aus einer Cochlea wurden durchschnittlich 0,5–1,2 µl Endo- und 5 µl Perilymphe gewonnen.

Die Bestimmung des Antibiotikagehaltes erfolgte auf bakteriologischem Wege durch Messung der antibiotischen Aktivität. Es wurde das allgemein in der Bakteriologie übliche Agar-Diffusionsverfahren angewendet, und zwar bei Serum und Gewebe in Form des Lochtestes und bei den Lymphen mit Hilfe des Blättchentestes. Verwendet wurden Filterblättchen Nr. 22 (Schleicher & Schüller) mit einem Durchmesser von 5 mm. Als Teststamm diente *Bact. subtilis* ATCC 6633. Die niedrigste feststellbare Kanamycin-Konzentration betrug im Serum und Gewebe 0,01 µg/ml bzw. 0,01 µg/g Frischgewicht, in der Innenohrlymphe 0,5 µg/ml. Die niedrigste feststellbare Neomycin-Konzentration betrug 1 µg/ml in Serum und Organen, aber nur 5 µg/ml in der Innenohrlymphe. Die Nachweisgrenzen für Colistin lagen bei 0,01 bzw. für die Lymphe bei 3 µg/ml, für Penicillin bei 0,01 IE/ml bzw. 0,2 IE/ml Lymphe.

Die mittlere Abweichung und die statistische Signifikanz der gemessenen Werte wurden hier wie auch bei den folgenden Versuchen unter Berücksichtigung der Anzahl der Versuche ($N < 100$) nach der T-Verteilung ermittelt.

Ergebnisse

Im Verhalten der Streptomycysantibiotika im Blutserum und in der Perilymphe des Innenohres lassen sich einige bemerkenswerte Unterschiede feststellen. Unmittelbar nach einer subkutanen Injektion von 250 mg Kanamycin/kg kommt es zu einem sehr schnellen Anstieg des Blutspiegels.

Die Serumkonzentration des Kanamycins betrug bereits nach 10 min 250 µg/ml und erreichte schon nach 1/2 Stunde ihr Maximum mit 800 µg/ml. Fast genauso schnell wie der Anstieg erfolgte auch die Eliminierung des Kanamycins aus dem Blut. 1 Stunde nach der Injektion war bereits eine deutliche Abnahme des Blutserumspiegels feststellbar. Die Halbwertszeit des Kanamycins im Blut betrug nur 85 min. Dieser Wert stimmt mit den Angaben anderer Autoren überein. Sousa (zit. bei Mückter 1961) fand für Dihydrostreptomycin beim Kaninchen eine Halbwertszeit von 80 min und Dost (1963) beim Menschen von 72 min.

In den Innenohrflüssigkeiten verhält sich Kanamycin dagegen ganz anders.

Abb. 5 zeigt zum Vergleich die Kanamycinspiegel des Serums und der Innenohrflüssigkeiten. Entgegen den bisherigen Vorstellungen erreicht Kanamycin im Innenohr überraschend hohe Konzentrationen. Bei einem Vergleich der Kanamycinkonzentrationskurven des Blutes und des Innenohres muß man feststellen, daß offenbar keine direkte Abhängigkeit vom Blutspiegel zu bestehen scheint. Es sieht so aus, als herrschten im Innenohr sowohl hinsichtlich der Anreicherung als auch bei der Ausscheidung des Kanamycins andere Gesetzmäßigkeiten vor. Im Gegensatz zu dem schnellen Anstieg des Blutspiegels nimmt die Kanamycinkonzentration der Innenohr-

Abb. 5 Kanamycinspiegel im Serum, in der Perilymphe und im Herzmuskel nach einmaliger Injektion, 250 mg/kg. (Alle Werte beziehen sich auf die Kanamycin Base)

flüssigkeiten auffallend langsam zu Kanamycinsulfat erreicht hier erst nach 1–2 Stunden, andere Antibiotika der Aminoglykosidgruppe wie Streptomycin oder die verschiedenen Pantothenatsalze des Kanamycins, auf die anschließend näher eingegangen werden soll sogar noch später nach 2–5 Stunden ihren höchsten Wert zu einem Zeitpunkt also, wo bereits ein wesentlicher Teil des Antibiotikums wieder aus dem Blut eliminiert ist.

Noch mehr als der Anreicherungsprozeß verdient vor allem der verzögerte Abtransport der toxischen Substanzen aus dem Innenohr Beachtung. Während der Kanamycinspiegel im Blutserum sehr schnell sinkt, bleiben die hohen Kanamycinkonzentrationen in den Innenohrflüssigkeiten über eine erstaunlich lange Zeit erhalten. Sie zeigen nur eine geringe Tendenz zur Abnahme. Die Halbwertszeit des Kanamycins ist im Innenohr mit annähernd 15 Stunden 10 mal länger als im Blut. Wie aus der Abb. 5 zu erkennen ist, war der Kanamycinspiegel im Blutserum nur verhältnismäßig kurze Zeit wesentlich höher als in den Innenohrflüssigkeiten. Bereits 5 Stunden post inj. enthielt das Innenohr fast 3 mal soviel und nach 25 Stunden sogar 15 mal soviel Kanamycin wie das Blutserum. Die Abb. 5 zeigt deutlich die viel flacher verlaufende Ausscheidungskurve des Kanamycins in der Perilymphe, welche die steil abfallende Blutkonzentrationskurve in charakteristischer Weise überschneidet. Dieser Kurvenverlauf kann als ein typisches Zeichen für einen kumulativen bzw. Retentionsprozeß im Innenohr angesehen werden.

Wie extrem hoch der Kanamycingehalt der Innenohrflüssigkeiten in Wirklichkeit ist, kommt am besten bei einem Vergleich mit anderen Organen zum Ausdruck (Tab. 1). 5 Stunden nach einer einmaligen subkutanen Injektion von 250 mg Kanamycin/kg fand sich in den Innenohr-

TABELLE 1 Vergleich des Kanamycingehaltes verschiedener Organe

Std. post Inject	Perilymphe	Endo- lymphe	Serum	Herz	Leber	Hirnstamm	Großhirn
5	22,5	18	9,2	0,71	0,65	0,150	0,121
18	12,0	11	0,7	0,44	0,39	0,10	0,055

γ Kanamycin-Baum/ ml bzw g. Organ (Frischgewicht)

flüssigkeiten z. B. 20 mal soviel Kanamycin wie im Herz, 50 mal soviel wie in der Leber und über 100 mal mehr als im Gehirn

Dieses Verhältnis verschleift sich 18 Stunden post inj bemerkenswerter weise noch weiter zugunsten der Innenohrlymphe. Zu diesem Zeitpunkt ist die Kanamycinkonzentration, wie aus der Tabelle hervorgeht, fast 50 mal so hoch wie im Herz und in der Leber und sogar 500 mal höher als im Gehirn. Das bedeutet, der Abtransport des Kanamycins aus dem Innenohr erfolgt trotz der hohen Konzentration und des günstigeren Diffusionsgefälles zum Blut und den benachbarten Geweben hin langsamer als die Eliminierung der geringen Kanamycinspuren aus den übrigen Organen.

Man könnte hier einwenden, daß ein derartiger Vergleich zwischen Innenohrflüssigkeiten und anderen Organen nicht möglich ist. Zwar repräsentiert die Innenohrlymphe, die mehr als 90% des gesamten Innenohres ausmacht, praktisch volumenmäßig das Innenohrorgan. Das Verhältnis Extrazellulärraum zu zellulären Elementen ist im Innenohr jedoch besonders extrem zugunsten der extrazellulären Flüssigkeiten verschoben. Da die Streptomycinantibiotika, wie bereits erwähnt wurde, überwiegend extrazellulär vorkommen, könnte die hohe Antibiotikakonzentration im Innenohr allein schon durch den großen Extrazellulärraum des Innenohres erklärt werden. Genauso ließe sich der geringe Antibiotikagehalt der Organe auf ihren verhältnismäßig kleinen extrazellulären Raum zurückführen. Nach Cardozo und Edelman (Thiosulfatmethode) macht das gesamte extrazelluläre Wasser 18,6% des Körpergewichtes aus, nach Levitt und Gaudino (Inulinmethode) 15%. Demnach enthalten z. B. Herz oder Leber nur etwa 1/8 soviel Wasser wie das Innenohr. Diese Organe müssen daher zwangsläufig entsprechend weniger Kanamycin enthalten. Aber selbst bei Berücksichtigung dieser Relation Extrazellulärraum zur Zelle bleibt die Antibiotikakonzentration im Innenohr immer noch um ein Vielfaches höher als in anderen Organen, vor allem wenn der Blutgehalt der Organe noch berücksichtigt wird.

Besonderes Interesse verdient der erhebliche Unterschied zwischen dem Kanamycingehalt der Perilymphe und des Z.N.S. Im Großhirn und vestibulären Kerngebiet des Hirnstammes konnten im Vergleich zum Innenohr nur Spuren von Kanamycin nachgewiesen werden. Vor allem war auch kein Unterschied zwischen dem Kanamycingehalt des Großhirns und des

Hirnstaumgebletes erkennbar. Diesem Befund kommt im Hinblick auf die gegensätzlichen Auffassungen über den Schädigungsort der Streptomycosubstanzen besondere Bedeutung zu. Wie bereits erwähnt wurde, nehmen einige Untersucher eine zentrale Schädigung im Kerngebiet an. Nach Ansicht der meisten Autoren allerdings ist der primäre Angriffsort überwiegend oder sogar ausschließlich im peripheren Sinnesapparat zu suchen. Nur bei extrem hohen Dosierungen lassen sich im ZNS morphologisch faßbare Veränderungen erkennen. Die letztere Auffassung findet durch unsere Untersuchungen eine weitere Stütze. Der hundertfach höhere Kanamycinpiegel des Innenohres spricht für eine primäre Schädigung des peripheren Hör- und Gleichgewichtsorganes. Kanamycin war im Gehirn nur in so geringen Mengen vorhanden, die kaum in der Lage sein dürften, hier Schädigungen hervorzurufen. Insbesondere wiesen auch die angeblich bevorzugt geschädigten Kerngebiete keinen höheren Kanamycingehalt auf, der eine bevorzugte Intoxikation dieses Hirnabschnittes erklären könnte.

Um über den Intoxikationsmechanismus eine genauere Aussage machen zu können, genügt nicht nur die Bestimmung des Kanamycins in der Perilymphe. Vor allem war es entscheidend zu wissen, wieviel Kanamycin in die Endolymphe und damit in unmittelbaren Kontakt mit dem Cortiorgan gelangt. Diese Frage ist insofern berechtigt, da Perilymphe und Endolymphe durch die Reissner'sche Membran vollständig von einander getrennt sind und bekanntlich erhebliche Unterschiede z. B. in ihrer Ionenzusammensetzung aufweisen. So enthält die Perilymphe überwiegend Natrium und nur wenig Kalium, während die Endolymphe umgekehrt sehr viel Kalium, aber nur wenig Natrium besitzt. Aus diesem Grunde war der große Arbeitsaufwand, der mit der Endolymphgewinnung verbunden ist, für eine genaue Klärung der ototoxischen Wirkung unumgänglich. Überraschenderweise zeigte es sich aber, daß der Kanamycingehalt der Endolymphe stets weitgehend dem der Perilymphe entspricht. Geringe Konzentrationsunterschiede lagen im normalen Schwankungsbereich der angewandten Untersuchungsmethoden und ließen sich statistisch nicht sichern. Die auffallende Übereinstimmung der Kanamycinkonzentrationen in der Peri- und Endolymphe könnte ein Hinweis dafür sein, daß wahrscheinlich eine Diffusion durch die Reissner'sche Membran hindurch stattfindet, die zu einem Konzentrationsausgleich führt. Die unterschiedlichen Kalium- und Natriumkonzentrationen in der Peri- und Endolymphflüssigkeit schließen einen Diffusionsvorgang nicht unbedingt aus. Es ist durchaus vorstellbar, daß in den Lymphräumen neben einem sog. aktiven Transport auch passive Diffusionsvorgänge stattfinden. Der Kalium- und Natriumtransport und damit der Aufbau des Endolymphpotentials beruht wahrscheinlich auf dem bekannten Mechanismus der K^+ - Na^+ -Pumpe, also auf einer aktiven Zellleistung. Die ausschließlich extrazellulär vorkommenden unphysiologischen Substanzen wie die Streptomycosantibiotika müssen dagegen auf einem anderen Wege wahrscheinlich über die Interzellularspalten die Reissner'sche Membran passieren. Dieser Permeationsvorgang scheint von der Zellfunk-

Abb 8: a und b Vergleich der Kanamycinspiegel im Blutserum, Herzserum und in der Perilymphe bei verschiedenen Dosierungen. (Alle Werte beziehen sich auf die Kanamycin-Base)

von unabhängig zu sein und nur den Gesetzen der Diffusion zu unterliegen.

Mit der hohen Konzentration und der langen Verweildauer der toxischen Substanzen vor allem auch in der Endolymphe sind alle Voraussetzungen für eine direkte Einwirkung auf die Sinneszellen des Innenohres erfüllt.

V Die Beziehung zwischen der Kanamycindosis und den Blut-, Gewebe- und Innenohrspiegeln

Die bisherigen Untersuchungen wurden mit relativ hohen und sicher toxischen Kanamycindosen von 230 mg/kg durchgeführt. Diese für das Tier

Hirnstammgebietes erkennbar. Diesem Befund kommt im Hinblick auf die gegensätzlichen Auffassungen über den Schädigungsort der Streptomycosubstanzen besondere Bedeutung zu. Wie bereits erwähnt wurde, nehmen einige Untersucher eine zentrale Schädigung im Kerngebiet an. Nach Ansicht der meisten Autoren allerdings ist der primäre Angriffsort überwiegend oder sogar ausschließlich im peripheren Sinnesapparat zu suchen. Nur bei extrem hohen Dosierungen lassen sich im ZNS morphologisch faßbare Veränderungen erkennen. Die letztere Auffassung findet durch unsere Untersuchungen eine weitere Stütze. Der hundertfach höhere Kanamycinspiegel des Innenohres spricht für eine primäre Schädigung des peripheren Hör- und Gleichgewichtsorganes. Kanamycin war im Cehlrn nur in so geringen Mengen vorhanden, die kaum in der Lage sein dürften, hier Schädigungen hervorzurufen. Insbesondere wiesen auch die angeblich bevorzugt geschädigten Kerngebiete keinen höheren Kanamycingehalt auf, der eine bevorzugte Intoxikation dieses Hirnabschnittes erklären könnte.

Um über den Intoxikationsmechanismus eine genauere Aussage machen zu können, genügte nicht nur die Bestimmung des Kanamycins in der Perilymphe. Vor allem war es entscheidend zu wissen, wieviel Kanamycin in die Endolymphe und damit in unmittelbaren Kontakt mit dem Cortiorgan gelangt. Diese Frage ist insofern berechtigt, da Perilymphe und Endolymphe durch die Reissner'sche Membran vollständig voneinander getrennt sind und bekanntlich erhebliche Unterschiede z. B. in ihrer Ionenzusammensetzung aufweisen. So enthält die Perilymphe überwiegend Natrium und nur wenig Kalium, während die Endolymphe umgekehrt sehr viel Kalium, aber nur wenig Natrium besitzt. Aus diesem Grunde war der große Arbeitsaufwand, der mit der Endolymphgewinnung verbunden ist, für eine genaue Klärung der ototoxischen Wirkung unumgänglich. Überraschenderweise zeigte es sich aber, daß der Kanamycingehalt der Endolymphe stets weitgehend dem der Perilymphe entsprach. Geringe Konzentrationsunterschiede lagen im normalen Schwankungsbereich der angewandten Untersuchungsmethoden und ließen sich statistisch nicht sichern. Die auffallende Übereinstimmung der Kanamycinkonzentrationen in der Peri- und Endolymphe könnte ein Hinweis dafür sein, daß wahrscheinlich eine Diffusion durch die Reissner'sche Membran hindurch stattfindet, die zu einem Konzentrationsausgleich führt. Die unterschiedlichen Kalium- und Natriumkonzentrationen in der Peri- und Endolymphflüssigkeit schließen einen Diffusionsvorgang nicht unbedingt aus. Es ist durchaus vorstellbar, daß in den Lymphräumen neben einem sog. aktiven Transport auch passive Diffusionsvorgänge stattfinden. Der Kalium- und Natriumtransport und damit der Aufbau des Endolymphpotentials beruht wahrscheinlich auf dem bekannten Mechanismus der K^+Na^+ -Pumpe, also auf einer aktiven Zellstung. Die ausschließlich extrazellulär vorkommenden, unphysiologischen Substanzen wie die Streptomycosantibiotika müssen dagegen auf einem anderen Wege, wahrscheinlich über die Interzellularspalten, die Reissner'sche Membran passieren. Dieser Permeationsvorgang scheint von der Zellfunk-

Abb. 7 Beziehung zwischen Kanamycin-Dosis und Kanamycin-Konzentration in der Perilymphe (Alle Werte beziehen sich auf die Kanamycin-Base.)

Eine nochmalige Steigerung der Dosis sogar um das 5-fache auf 250 mg/kg, führt, wie die folgende Abb. 7 zeigt, nur noch zu einem entsprechenden Anstieg des Blut- und Gewebespiegels. Trotz des 5 mal so hohen Blutspiegels nahm jetzt die Konzentration des Kanamycins im Innenohr nicht mehr weiter zu. Es sieht so aus, als käme der Anreicherungsprozeß für Kanamycin im Innenohr mit zunehmender Dosierung nach einem anfänglichen kurzen aber steilen Anstieg zum Stillstand. Das Verhältnis Kanamycin-Dosis zur Kanamycinanreicherung im Innenohr wird durch eine steile Sättigungskurve charakterisiert. Dagegen scheint zwischen der applizierten Dosis und dem Blutspiegel nur eine einfache lineare Beziehung zu bestehen (Abb. 8).

Dieser Befund fordert zu mehr oder weniger spekulativen Betrachtungen heraus, auf die später noch eingegangen werden soll. Er ist darüber hinaus auch für die praktische Anwendung und Dosierung der Streptomycesantibiotika von Bedeutung, weil er zeigt, wie gerade in dem therapeutisch in Betracht kommenden Dosierungsbereich schon geringfügige Dosiserhö-

experiment übliche Dosierung ist aber wie man mit Recht einwendet therapeutisch uninteressant. Für die Praxis ist es vielmehr von Bedeutung, zu wissen wie sich Kanamycin im therapeutischen Dosisbereich verhält, oder welche Folgen eine längere Behandlung hat.

1 Die Bedeutung der Eln eldosix für die Blut und Organkon entration

Betrachten wir zunächst die Beziehung zwischen der Höhe der Kanamycindosis und den Blut- Gewebe- und den Innenohrspiegeln. Durch eine einmalige Gabe von nur 15 mg Kanamycin/kg läßt sich ein Blutspiegel von ungefähr 20 γ /ml Blutsrum erzielen. Eine Erhöhung der Dosis auf 25 mg/kg führt wie die Abb. 6 zeigt, zu einer entsprechenden Erhöhung der Blutkonzentration auf 36 γ /ml.

Ebenso und offensichtlich in Abhängigkeit vom Blutspiegel nimmt auch der Kanamycingehalt der Organe zu, wenn auch die Gewebsspiegel vergleichsweise sehr gering sind. Die Kanamycinkonzentration im Herzmuskel erreichte nicht einmal 1 γ /g, wobei sicher noch der größte Anteil auf den hohen Blutgehalt dieses Organes zurückzuführen ist. In der Leber fand sich nur 1/10 davon, also 0,1 γ /g, ein Wert, der auf dieser Abb. nicht mehr darzustellen war. Im Gehirn konnte überhaupt kein Kanamycin festgestellt werden, d. h., die Konzentration lag unter der Nachweisgrenze von 0,01 γ /g. Nur die Innenohrflüssigkeiten wiesen schon bei einer Dosierung von 15 mg/kg 2,0 γ /ml und bei 25 mg/kg 2,5 γ /ml Perilymphe auf. Dieser relativ hohe Kanamycingehalt der Innenohrflüssigkeit ist umso beachtenswerter, wenn man außerdem die Halbwertszeit im Innenohr berücksichtigt, die länger ist als in allen anderen Organen und vor allem auch viel länger als im Blut. Während Kanamycin z. B. 5 Stunden post inj. wieder weitgehend bis auf einen geringen Rest von 0,14 γ /ml aus dem Blut eliminiert war, betrug der Kanamycingehalt der Innenohrflüssigkeiten zu diesem Zeitpunkt immer noch 1,9 γ /ml und übertraf damit den Blutspiegel um mehr als das 10-fache. Es fällt also schon bei niedrigen Dosen eine Anreicherung bzw. Retention des Kanamycins im Innenohr auf.

Wir hatten bereits auf das unterschiedliche Verhalten des Kanamycins im Blutsrum und in den Innenohrflüssigkeiten hingewiesen und hieraus den Schluß gezogen, daß im Innenohr wahrscheinlich ein besonderer Mechanismus vorliegen muß, der sowohl für den deutlichen langsameren Anreicherungsprozeß als auch für den erheblich verzögerten Abtransport aus den Innenohrräumen verantwortlich ist. Dieses eigentümliche Verhalten der Streptomycysantibiotika kam bei weiteren Versuchen noch deutlicher zum Ausdruck.

Erhöht man nämlich die Kanamycindosis von 25 mg/kg auf 50 mg/kg, so zeigt sich zwar erwartungsgemäß ein doppelt so hoher Blutspiegel und auch eine entsprechende Erhöhung der Kanamycinkonzentration im Gewebe z. B. des Herzmuskels wie auf der Abb. 6a zu sehen ist. Überraschenderweise stieg aber der Kanamycingehalt der Perilymphe viel stärker, ja geradezu sprunghaft um ungefähr das 10-fache an.

weiteren signifikanten Zunahme der Innenohrkonzentration um insgesamt 137% vom Ausgangswert. Hier zeigt sich eine interessante Erklärung für eine aus der Praxis längst bekannte Erfahrungstatsache. Die besondere Gefahr bei einer Langzeitbehandlung mit Streptomycsanthibiotika beruht demnach nicht etwa auf einer einfachen Summation der Schädigungen, sondern wahrscheinlich in erster Linie auf der Tatsache, daß mit jeder weiteren Injektion das jeweilige Maximum des Innenohrspiegels langsam aber stetig zunimmt.

Für den Anstieg der Innenohrkonzentration bei gleichbleibender Dosierung kommen verschiedene Ursachen in Betracht. Zunächst muß eine renal bedingte Ausscheidungsstörung z. B. infolge einer toxischen Nierenschädigung ausgeschlossen werden. Dieser Fehler unterlief z. B. Voldrich, als er ähnliche Untersuchungen mit dem besonders oto- und nephrotoxischen Neomycin durchführte und dabei schon nach wenigen Injektionen extrem hohe Innenohrspiegel fand. Tatsächlich handelte es sich hier aber wie wir nachweisen konnten, nicht um einen organspezifischen Anreicherungsprozeß, sondern um eine Störung der renalen Ausscheidung. Als Ausdruck einer gestörten Nierenfunktion bleiben die Blutspiegel, die normalerweise schon nach einer halben Stunde wieder abnehmen, unter Neomycin während der ganzen Versuchsdauer auf ihrer maximalen Höhe bestehen. Daß unter diesen Bedingungen hohe Innenohrkonzentrationen auftreten, die genauso lange andauern wie der Blutspiegel, ist daher nicht weiter verwunderlich. — Bei den oben geschilderten Dauerbehandlungen mit Kanamycin wurde jedoch weder der Blut- noch der Gewebesspiegel in irgend einer Weise beeinflußt. Sie verhielten sich nach 20 Injektionen genau wie nach der ersten. Eine renale Ausscheidungsstörung kann also hier nicht zur Erklärung herangezogen werden.

Als nächstes mußte man daran denken, daß vielleicht die erheblich verzögerte Ausscheidung des Kanamycins für die Konzentrationszunahme bei einer Dauerbehandlung verantwortlich ist. Die Eliminierung des Kanamycins ist wie auch aus der Abb. 5 hervorgeht, nach 25 Stunden bei weitem noch nicht abgeschlossen. Es finden sich am nächsten Tage, an dem in üblicher Weise bereits die nächste Injektion erfolgt, noch ungefähr 10% des Kanamycins vom Vorlage in den Innenohrflüssigkeiten. Eine 2. Injektion muß daher zwangsläufig zu einem höheren Innenohrspiegel führen. Durch einen stetig wachsenden Rückstau an Kanamycin würde somit die Kumulation eine Erklärung finden. Es stellte sich aber heraus, daß mit steigender Innenohrkonzentration die Kanamycinrückstände im Innenohr nicht in dem Maße wie man es erwarten sollte zunehmen. Vielmehr zeigte es sich, daß je höher die Innenohrkonzentration ist, umso schneller auch die Ausscheidung erfolgt. Das bedeutet, mit steigendem Kanamycingehalt im Innenohr nimmt die ausgeschleuderte Kanamycinmenge pro Zeiteinheit zu, so daß eine fortschreitende Retention der toxischen Substanzen wie es die Abb. 5 zeigt, weitgehend verhindert wird. Nach 18 bzw. 25 Stunden post inj. erreicht der Perilymphspiegel, auch wenn er wesentlich höher war

Abb. 8 Beziehung zwischen Kanamycindosis und Kanamycin Blutkonzentration.

hungen einen unverhältnismäßig hohen Anstieg der Antibiotikakonzentration im Innenohr zur Folge haben. Diese plötzliche Zunahme des Antibiotikagehaltes stellt wahrscheinlich die toxische Schwelle des Innenohres dar. Die kritische Schwellendosis liegt dessen sollte man sich stets bei einer Behandlung mit den toxischen Streptomycosanibiotika bewußt sein, noch im sog. therapeutischen Bereich. Die klinisch schon lange bekannte Tatsache, daß die therapeutische Breite dieser Substanzgruppe außerordentlich gering ist, findet durch diesen Befund ihre Bestätigung und Erklärung.

2 Der Einfluß einer Dauerbehandlung mit Streptomycosanibiotika auf die Blut-, Gewebe- und Innenohrspiegel

Obwohl der Perilymphspiegel schon nach einer einmaligen Injektion von 200 mg/kg Kanamycin einen Höchstwert erreicht zu haben schien, zeigte es sich, daß das Innenohr unter bestimmten Umständen in der Lage ist, noch mehr Kanamycin aufzunehmen. Verabfolgt man die gleiche Kanamycindosis 10 oder 20 mal in täglichen Abständen, so kann man, wie die Abb. 9 zeigt, eine weitere erhebliche Steigerung der Kanamycinkonzentration erzielen.

Die Zunahme mag zwar verglichen mit dem steilen Anstieg im niedrigen Dosisbereich, wie wir es oben sehen, relativ gering erscheinen. Der absolute Zuwachs ist trotzdem beachtenswert und sicher auch in tierischer Hinsicht nicht bedeutungslos. Nach einer 10-tägigen Behandlung mit einer Tagesdosis von 200 mg/kg konnten wir einen statistisch zu sichernden Anstieg des Kanamycingehaltes in den Innenohrflüssigkeiten von 50-fach stellen. Nach 20 Injektionen der gleichen Dosis kam es nochmals zu einer

VI Zur Ursache der Anreicherung und verzögerten Ausscheidung der Aminoglykosidantibiotika

Bevor wir uns der Frage zuwenden, warum die toxischen Substanzen ausgerechnet im Innenohr angereichert werden, muß man sich zunächst einmal die Frage stellen, wie sich normalerweise andere Stoffe, seien es solche mit guten oder schlechten Resorptionseigenschaften, im Innenohr verhalten.

Beretta Portmann, Geraud, Morin, Jancko und Blanquet (1960) und Rauch (1960) machten die Feststellung, daß markiertes Natrium nach intravenöser Injektion relativ schnell in die Perilymphe des Innenohres gelangt, seine Entfernung aus den Innenohrräumen aber verglichen mit dem Blutspiegel deutlich verzögert ist. So kommt es, daß die Perilymphe einige Stunden nach der Injektion bis zu 176 mal soviel Na^{22} enthält wie das Blut. Dieses Verhältnis zwischen Blut und Perilymphe bleibt über 48 Stunden konstant. Es stellt sich also ein Gleichgewicht zwischen Blut und Innenohrflüssigkeit ein.

Ähnliche Versuche führte Schreiner mit P^{32} -markiertem Phosphat (1961) und mit J^{125} -markiertem Albumin (1966) durch. Hierbei zeigte sich aber, daß der Perilymphspiegel der Phosphate und auch des Albumins stets erheblich unter der Blutkonzentration lag. Die Ionen scheinen in dieser Hinsicht eine Ausnahme zu machen.

In Anbetracht der großen Unterschiede, die diese Substanzen sowohl in biochemischer als auch in physiologischer Hinsicht aufweisen, ist eine Deutung der Befunde sehr schwierig. Bei der Verteilung dieser Stoffe im Organismus und auch im Innenohr müssen verschiedene Faktoren, wie z. B. ihre Reaktionsfähigkeit und ihr Stoffwechsel, ihre Molekülgröße und ihre unterschiedlichen Permeationsmöglichkeiten, seien es aktiver Transport oder passive Vorgänge berücksichtigt werden.

1 Die Untersuchung der Inulinclearance des Innenohres

Um eine genauere Aussage über den Stoffaustausch in den Innenohrflüssigkeiten machen zu können, war es daher erforderlich, Substanzen zu erwenden, die sich durch genau definierte und überschaubare Eigenschaften auszeichnen. Es lag nahe, solche Substanzen für die Untersuchung im Innenohr heranzuziehen, wie sie auch bei Clearanceuntersuchungen der Niere Anwendung finden. Wir wählten hier das Inulin, das den Vorzug hat, weitgehend chemisch indifferent und sehr stabil zu sein. Darüber hinaus besitzt Inulin als Substanz des extrazellulären Raumes den Vorzug, weder resorbiert noch sezerniert zu werden. Für die Verteilung des Inulins im Organismus kommen nur Filtrations- und Diffusionsvorgänge in Betracht. Auf Grund dieser Eigenschaften hat Inulin eine große Bedeutung zur Bestimmung des Extrazellulärraumes und der Filtrationsgröße der Niere erlangt. Bei unseren Versuchen erwarteten wir vom Inulin Aufschluß darüber, ob und in welchem Ausmaß Diffusions- und Filtrationsvor-

Abb 9 Kanamycinspiegel in der Perilymphe nach 1 (—x—) = ch 10 (—O—) und 20 (—•—) täglichen Injektionen v = 250 mg Kanamycinsulf t/kg (Alle Werte beziehen sich auf die Kanamycin II se)

annähernd wieder den gleichen Ausgangswert. Die Abhängigkeit der Ausscheidungsgeschwindigkeit vom Konzentrationsgefälle spricht dafür, daß die Eliminierung der Streptomycinsantibiotika wahrscheinlich nach den Gesetzen der Diffusion vor sich geht.

Der außergewöhnlich langsam verlaufende Abtransport der toxischen Substanzen aus dem Innenohr kann demnach nicht allein für die zunehmende Konzentration bei einer Dauerbehandlung verantwortlich sein. Viel mehr scheint ein Zusammenhang zwischen der fortschreitenden Intoxikation und dem Anstieg der Kanamycinkonzentration zu bestehen. Vor allem sind hier toxische Schädigungen an den Innenohrmembranen in Erwägung zu ziehen, die möglicherweise den Anreicherungsprozeß des Kanamycins mit begünstigen. Man muß hier i. C. zu den anfangs erwähnten Untersuchungen, wo lediglich eine einmalige Injektion verabreicht wurde, bedenken, daß wir bei einer Dauerbehandlung mit mehr oder weniger vorgeschädigten Membranen zu rechnen haben. Es ist anzunehmen, daß nach 2 Stunden, wenn die nächste Injektion erfolgt, noch Membranpermeabilitätsstörungen vorliegen, die eine Anreicherung des Kanamycins fördern. Die steigende Konzentration im Verlaufe der Behandlung wäre demnach Ausdruck einer zunehmenden toxischen Schädigung des Innenohres. Es liegt hier offenbar ein *Circulus vitiosus* vor. Je höher der Kanamycinspiegel im Innenohr, umso ausgeprägter sind die toxischen Schädigungen. Je stärker aber die Schädigung, umso mehr Kanamycin wird wiederum angereichert.

erfolgte auf die übliche, bereits beschriebene Weise in der Tiefkühlkammer nach Homogenisierung und Aufbereitung des Materials mit Nymalinhydroxyd in einem kochenden Wasserbad und anschließender Zugabe von Diolal erfolgte die Messung in einem Tricarb-Scintillationszähler. Der hierbei entstehende Quanten-Effekt ließ sich anhand einer Eichkurve eliminieren. Die gemessene Impulszahl pro Minute wurde auf das Frischgewicht der Organe bezogen.

Wie Abb. 10 zeigt, gelangt Inulin trotz seines hohen Molekulargewichtes von 6000 offensichtlich ohne Schwierigkeiten in das Innenohr. Das bedeutet, da eine Sekretion ausgeschlossen werden kann, daß der Eintritt in die Innenohrräume entweder durch Filtration oder über eine Diffusion erfolgen muß. Dieser Befund ist für die Physiologie des Innenohres von Interesse, da bis in die jüngste Zeit hinein die Auffassung vorherrschte, daß die Innenohrflüssigkeiten ein Sekretionsprodukt z. B. der *Stria vascularis* darstellen. Die Inulinversuche sprechen vielmehr für die neuerdings von Schindler wiederaufgegriffene Theorie, wonach zumindest die Perilymphe als ein Ultrafiltrat des Blutes anzusehen ist. In Anbetracht des etwa gleich hohen Inulingehaltes der Endolymphe drängt sich die Frage auf, ob nicht auch für die Endolymphebildung Filtrationsvorgänge oder eine Diffusion aus dem Perilymphraum durch die Reissner'sche Membran verantwortlich sind.

Der Inulinversuch vermittelt nicht nur einen Einblick in die Entstehung der Innenohrflüssigkeiten, sondern darüberhinaus auch in ihren Austausch. Die nicht resorbierbaren Stoffe wie Inulin gelangen zwar leicht in die Innenohrräume, aber offensichtlich nur schwer wieder heraus. Verglichen mit anderen gut resorbierbaren Stoffen bleibt Inulin viel länger im Innenohr zurück und erreicht hier Konzentrationen, die mehr als das Doppelte des Blutspiegels ausmachen. Die Anreicherung des Inulins kann wahrscheinlich darauf zurückgeführt werden, daß es aus dem Innenohr nicht aktiv rückresorbiert wird, sondern nur diffundieren kann. Demgegenüber scheinen gut resorbierbare Stoffe leichter eliminierbar zu sein, da sie zusätzlich der aktiven Rückresorption durch die Zellen der *Stria vascularis* oder des *Ductus endolymphaticus* unterliegen. Dieser Ausweg aus dem Innenohr steht dem Inulin nicht zur Verfügung. Das Verhalten des Inulins, so man auch als Inulinclearance des Innenohres bezeichnen könnte, zeigt, wie weit ein Stoffaustausch im Innenohr allein durch Filtration und Diffusion und unabhängig von aktiven Resorptions- und Sekretionsprozessen möglich ist.

Die Kumulation der Aminoglykosidantibiotika im Innenohr

Darüberhinaus bringen uns die Inulinbefunde auch einer Erklärung der Kumulationsvorgänge bei den Streptomycesantibiotika näher. Kanamycin z. B. erreicht, wie oben bereits gezeigt wurde, in einer niedrigen Dosierung von 15 oder 2 mg/kg, die praktisch equimolar ist mit der oben angewandten Inulindosis, einen mit Inulin vergleichbaren Innenohrspiegel. Er beträgt ebenfalls 3 Stunden post inj. das 2,5-fache des Blutspiegels und

gange für den Stoffaustausch in den Innenohrflüssigkeiten in Betracht kommen

Neben diesen physiologischen Aspekten eignet sich Inulin im Rahmen unserer Untersuchungen deswegen ganz besonders gut, da es sehr ähnliche Eigenschaften aufweist wie die Aminoglykosidantibiotika. Daß beide chemisch Zuckerverbindungen darstellen sei hier nur am Rande bemerkt. Ein Vergleich des Inulins mit den Aminoglykosidantibiotika ist vor allem deswegen aufschlußreich, weil beide Substanzen bemerkenswerterweise die gleichen Permeationseigenschaften besitzen.

Methode

Für die Untersuchungen verwendeten wir C^{14} -markiertes Inulin-Carboxyl, das Meerschweinchen subkutan injiziert wurde. Wegen der außerordentlich kleinen Verhältnisse im Innenohr war es erforderlich um eine meßbare Menge zu erzielen, hohe Dosen von 35 mg Inulin mit einer Gesamtkonzentration von 0.1 mCi pro Tier zu verabreichen. Wegen der hohen Kosten mußte auf eine größere Versuchsserie verzichtet werden.

10 und 15 Stunden post inj erfolgte die Tötung der Tiere durch Dekapitation. Blut (wobei das Kopfblut und das Blut des übrigen Körpers getrennt gewonnen und die Seren abzentrifugiert wurden), Herz, Leber und Gehirn wurden entnommen. Die Präparation der Endo- und Perilymphe

Abb 10 Vergleich der Inulinkonzentration in Blutserum, der Innenohrflüssigkeiten und Organen. Die Werte beziehen sich auf die Perilymphe deren Konzentration mit 100 angenommen wurde.

erfolgte auf die übliche bereits beschriebene Weise in der Tiefkühlkammer nach Homogenisierung und Aufbereitung des Materials mit Hyaminhydroxyd in einem kochenden Wasserbad und anschließender Zugabe von Ditol erfolgte die Messung in einem Tricarb-Scintillationszähler. Der hier bei entstehende Quanten-Effekt ließ sich anhand einer Eichkurve eliminieren. Die gemessene Impulszahl pro Minute wurde auf das Frischgewicht der Organe bezogen.

Wie Abb. 10 zeigt, gelangt Inulin trotz seines hohen Molekulargewichtes von 6000 offensichtlich ohne Schwierigkeiten in das Innenohr. Das bedeutet, da eine Sekretion ausgeschlossen werden kann, daß der Eintritt in die Innenohrräume entweder durch Filtration oder über eine Diffusion erfolgen muß. Dieser Befund ist für die Physiologie des Innenohres von Interesse, da bis in die jüngste Zeit hinein die Auffassung vorherrschte, daß die Innenohrflüssigkeiten ein Sekretionsprodukt z.B. der *Stria vascularis* darstellen. Die Inulinversuche sprechen vielmehr für die neuerdings von Schindler wiederaufgegriffene Theorie, wonach zumindest die Perilymphe als ein Ultrafiltrat des Blutes anzusehen ist. In Anbetracht des etwa gleich hohen Inulingehaltes der Endolymphe drängt sich die Frage auf, ob nicht auch für die Endolymphbildung Filtrationsvorgänge oder eine Diffusion aus dem Perilymphraum durch die Reissner'sche Membran verantwortlich sind.

Der Inulinversuch vermittelt nicht nur einen Einblick in die Entstehung der Innenohrflüssigkeiten, sondern darüberhinaus auch in ihren Austausch. Die nicht resorbierbaren Stoffe wie Inulin gelangen zwar leicht in die Innenohrräume, aber offensichtlich nur schwer wieder heraus. Verglichen mit anderen gut resorbierbaren Stoffen bleibt Inulin viel länger im Innenohr zurück und erreicht hier Konzentrationen, die mehr als das Doppelte des Blutspiegels ausmachen. Die Anreicherung des Inulins kann wahrscheinlich darauf zurückgeführt werden, daß es aus dem Innenohr nicht aktiv rückresorbiert wird, sondern nur diffundieren kann. Demgegenüber scheinen gut resorbierbare Stoffe leichter eliminierbar zu sein, da sie zusätzlich der aktiven Rückresorption durch die Zellen der *Stria vascularis* oder des *Ductus endolymphaticus* unterliegen. Dieser Ausweg aus dem Innenohr steht dem Inulin nicht zur Verfügung. Das Verhalten des Inulins, das man auch als Inulin-clearance des Innenohres bezeichnen könnte, zeigt, wie weit ein Stoffaustausch im Innenohr allein durch Filtration und Diffusion und unabhängig von aktiven Resorptions- und Sekretionsprozessen möglich ist.

Die Kumulation der Aminoglykosidantibiotika im Innenohr

Darüberhinaus bringen uns die Inulinbefunde auch einer Erklärung der kumulationsvorgänge bei den Streptomycesantibiotika näher. Kanamycin z.B. erreicht, wie oben bereits gezeigt wurde, in einer niedrigen Dosierung von 15 oder 25 mg/kg, die praktisch equimolar ist mit der oben angewandten Inulindosis, einen mit Inulin vergleichbaren Innenohrspiegel. Er beträgt ebenfalls 6 Stunden post inj. das 2,5-fache des Blutspiegels und

KANAMYCIN IN PERILYMPHE

Abb 11 kanamycinkonzentration in Perilymphe und kanamycinsulfat Dosis. (Alle Werte bezogen auf kanamycin Base)

ein vielfaches der Organkonzentration. In diesem Dosisbereich weisen die beiden nicht resorbierbaren Substanzen das ungiftige Inulin und die toxischen Aminoglykosidantibiotika in ihrem Verhalten im Innenohr eine weitgehende Übereinstimmung auf. In der Anreicherung schwer resorbierbarer giftiger Stoffe im Innenohr ist wahrscheinlich die primäre Ursache für die Ototoxikose zu sehen. Sie geht der eigentlichen Innenohrschädigung voraus und könnte als die erste, einleitende Phase der Intoxikation bezeichnet werden (Abb 11).

Mit steigendem kanamycinegehalt wird schließlich eine toxische Schwellenkonzentration erreicht. In dem Augenblick, wo die Dosis von 25 mg/kg überschritten wird, tritt wie Abb 7 zeigt eine entscheidende Änderung im Verhalten des kanamycins auf. Wir haben sie in der Abb 11 als 2. Phase des Intoxikationsverlaufs bezeichnet. In diesem Stadium kommt es zu einem sprunghaften Anstieg der Innenohrkonzentration. Es besteht der Verdacht, daß die verstärkte Retention des kanamycins bereits Ausdruck einer toxischen Innenohrschädigung ist.

Wir neigen zu der Auffassung, daß es sich hier wahrscheinlich um die ersten Zeichen einer gestörten Permeabilität der Innenohrmembranen handelt. Diese Vorstellung stützt sich auf experimentelle Befunde und Untersuchungen, die zu Zi. noch weiter fortgesetzt werden, aber bereits Folgen des erkennen lassen. Es zeigte sich, daß der Transport markierter Kalium-Ionen, die in den Perilymphraum, die Scala vestibuli oder Scala tympani eingebracht worden waren und normalerweise sehr schnell durch die Reiss-

nerische Membran in die Endolymphe übertreten und dann von der Stria vascularis des Endolymphraumes aufgenommen werden, durch Kanamycin weitgehend zum Erliegen kommt. Kanamycin übertrifft in dieser permeabilitätsbehemmenden Eigenschaft sogar alle anderen bekannten Membrangifte wie Streptomycin G, Monojodessigsäure oder Salicylan, deren Wirkung auf das Innenohr wir bereits früher untersucht. Bemerkenswert ist, daß die ersten Zeichen einer herabgesetzten Durchlässigkeit der Membran in dem offenbar kritischen Dosisbereich über 25 mg/kg Kanamycin zu beobachten sind, also gerade in dem Augenblick, wo auch der erste Anstieg des Kanamycinspiegels im Innenohr erfolgt. Man kann hier aus auf einen ursächlichen Zusammenhang schließen. Die Annahme liegt nahe, daß die verminderte Membranpermeabilität für Kalium wahrscheinlich auch für die Anhäufung des Kanamycins verantwortlich ist.

Ebenso läßt sich auch die 3. Phase der Intoxikation, die durch den flachen Verlauf der Sättigungskurve, d. h., mit anderen Worten durch ein Stillstehen des Anreicherungsprozesses (Abb. 7 bzw. 11) charakterisiert wird, als einen Membraneffekt deuten. Sie könnte durch eine nunmehr vollständige Abdichtung der Innenohrmembranen nicht nur für Kanamycin, sondern auch für andere gut resorbierbare Stoffe wie z. B. für Ionen erklärt werden. Damit käme auch der Wassertransport im Innenohr zum Erliegen. Die Folge ist wahrscheinlich ein Stillstand der gesamten Lymphzirkulation und des Lymphanstromes im Innenohr, so daß keine neue Kanamycinhaltige Lymphe mehr in das Innenohr gelangt und der Anreicherungsorgang zum Erliegen kommen muß.

Die verschiedenen Phasen des Intoxikationsprozesses könnte man sich folgendermaßen vorstellen. Als erstes morphologisches Substrat der Intoxikation werden von allen Untersuchern übereinstimmend Zellvergrößerungen und Kernschwellungen beschrieben. Diese Veränderungen betreffen nicht nur die Haarzellen, sondern auch die Stütz- und Epithelzellen der Stria vascularis, also praktisch alle Zellen des Innenohres mehr oder weniger stark je nach ihrer Empfindlichkeit. Denkbar wäre, daß hierdurch zunächst nur eine Abdichtung der Innenohrmembranen, d. h., genauer gesagt ihrer interzellulären Spalten hervorgerufen wird, jenes Raumes also, der gerade für den Transport der überwiegend extrazellulären Substanzen wie Streptomycin von entscheidender Bedeutung ist. Auf diese Weise wird die Anreicherung der toxischen Antibiotika gehemmt und ihre Anhäufung im Innenohr gefördert. Kanamycin würde sich also in diesem Falle selbst, infolge einer toxischen Membranwirkung, den Ausweg aus dem Innenohr blockieren und wäre damit für seine vermehrte Anreicherung ursächlich verantwortlich. Die 2. Phase der Anreicherung ließe sich durch eine derartige erschwerte Diffusion zwanglos erklären. Erst in der 3. Phase scheint es dann mit dem Erlöschen der Zellfunktion zu einem Stillstehen auch der Ionen- und Flüssigkeitsaustausch behindert wird und schließlich zum Erliegen kommt.

Der charakteristische Verlauf der Kanamycinanreicherung im Innenohr könnte auch noch auf andere Weise gedeutet werden. Denkbar war z. B. eine Schranke zwischen Blut und Innenohrlymphe die erst bei einer bestimmten Kanamycinkonzentration im Blut überschritten werden kann. Gegen diese Hypothese ist jedoch einzuwenden, daß unterhalb der angenommenen Schwellenkonzentration bereits relativ große Kanamycinmengen in das Innenohr gelangen.

Als weitere Ursache für die Anhäufung wäre im Innenohr auch eine chemische Bindung des Kanamycins, z. B. an saure Substanzen der Innenohrlymphe vorstellbar. Die Sättigung könnte in diesem Falle als ein Erschöpfen der zur Verfügung stehenden Bindungskapazität aufgefaßt werden. Zur Klärung dieser Frage sind weitere Untersuchungen vor allem mit Hilfe der Dünnschichtchromatographie vorgesehen, die zeigen sollen, ob eine evtl. Kopplung des Kanamycins an Substanzen der Innenohrflüssigkeiten vorliegt. Gegen diese Annahme allerdings spricht, daß in anderen extrazellulären Flüssigkeiten eine solche Bindung nicht zu beobachten ist.

VII Vergleich der Kanamycin Streptomycin Dihydrostreptomycin und Neomycinspiegel im Organismus.

Die übrigen Antibiotika der Oligosaccharidgruppe Streptomycin, Dihydrostreptomycin und Neomycin unterscheiden sich hinsichtlich ihres Verhaltens im Organismus grundsätzlich nicht vom Kanamycin. Sie werden ebenfalls im Innenohr angereichert und nur sehr langsam wieder ausge-

schieden. Dennoch weisen sie einige bemerkenswerte Unterschiede auf die eine genauere Betrachtung wert sind.

Auf Abb 12 sind zum Vergleich die Perilymphspiegel der verschiedenen Streptomycesantibiotika dargestellt. Streptomycin weist hier verglichen mit den anderen Antibiotika dieser Gruppe bei gleicher Dosierung den niedrigsten Innenohrspiegel auf. Nur wenig höher verläuft die Konzentrationskurve des Kanamycins. Die geringe Differenz zwischen Kanamycin und Streptomycin ist nicht signifikant.

Auch der Blutspiegel des Dihydrostreptomycins entsprach weitgehend dem des Streptomycins. Dagegen fiel eine wesentlich höhere Konzentra-

tion des Dihydrostreptomycins sowohl im Innenohr als auch im Herz und in der Leber auf (Abb 13)

Die höheren Organ und Innenohrspiegel des Dihydrostreptomycins lassen sich gegenüber Kanamycin und Streptomycin statistisch sichern ($p < 0.005$). Aus diesen Befunden könnte man den Schluß ziehen, daß Dihydrostreptomycin nicht, wie vielfach angenommen wird ototoxischer ist als Streptomycin, sondern seine stärkere ototoxische Wirkung lediglich seiner höheren Konzentration am Schadensort verdankt. So findet auch die Tatsache, daß Dihydrostreptomycin trotz seiner geringeren akuten bzw. Allgemeintoxizität stärkere Innenohrschädigungen verursacht als Streptomycin eine Erklärung. Die Diskussion über diese umstrittenen und für die therapeutische Anwendung entscheidenden Vor- und Nachteile des DSM ging über viele Jahre hin und führte schließlich zum Verbot des Dihydrostreptomycins. — Es muß jedoch hinzugefügt werden, daß ein höherer Dihydrostreptomycinspiegel bisher nur im Innenohr des Meerschweinchens aber noch nicht beim Menschen nachgewiesen werden konnte. Zwar soll nach Müsbeck DSM beim Meerschweinchen genauso wie beim Menschen stärkere Hörschädigungen hervorrufen als SM. Jedoch gehen hierüber die Ansichten der einzelnen Untersucher sehr auseinander so daß eine endgültige Beurteilung z. Zt. noch nicht möglich ist.

Sicherlich würde es zu weit führen, wollte man die unterschiedliche Toxizität der einzelnen Antibiotika der Aminoglykosidgruppe ausschließlich von ihrer Konzentration im Innenohr her erklären. Das würde letztlich bedeuten, daß sämtliche Stoffe, die gleiche Toxizität besitzen was aber kaum anzunehmen ist. Soviel darf aber heute auf Grund dieser Befunde schon gesagt werden, daß der Konzentration eine größere Bedeutung zukommen scheint als man bisher vermutete.

Allgemein wird heute zumindest beim Menschen das Streptomycin als das am wenigsten ototoxische Antibiotikum der Aminoglykosidgruppe angesehen. Danach folgt das Dihydrostreptomycin, Kanamycin und Neomycin. Vergleicht man diese Reihenfolge mit der Folge ihrer Konzentrationen im Innenohr wie sie auf Abb 12 dargestellt sind nämlich Streptomycin, Kanamycin, Dihydrostreptomycin und Neomycin, so fällt zwar eine große Ähnlichkeit auf, aber es besteht keine vollständige Übereinstimmung. So spricht vor allem gegen die bisherigen Vorstellungen die Tatsache, daß Kanamycin obwohl es stärker toxisch ist im Innenohr in einer geringeren Konzentration vorkommt als Dihydrostreptomycin. Von dieser Ausnahme abgesehen scheinen aber die Befunde besonders deutlich kommt dies am Beispiel des Neomycins zum Ausdruck auf eine Beziehung zwischen der Innenohrkonzentration der Antibiotika und ihrer Ototoxizität hinzuweisen.

Neomycin mußte im Rahmen dieser vergleichenden Untersuchungen in Folge seiner wesentlich stärkeren toxischen Wirkung in viel niedrigerer Dosierung angewandt werden als Kanamycin, SM und DSM. Obwohl am Anfang nur 100 mg Neomycin/kg verabreicht wurden war der Innenohrspiegel 4 mal so hoch wie bei einer $2\frac{1}{2}$ -fach höheren Kanamycin-

Abb. 14 Neomycinspiegel im Blutserum und in der Perilymphe nach einmaliger i. jekt. Gabe einer hohen nephrotoxischen Dosis (100 mg/kg)

Es liegt nahe die viel stärkere Otoloxizität des Neomycins auf die besonders ausgeprägte Kumulationsneigung dieser Substanz im Innenohr zurückzuführen. Diese Schlußfolgerung scheint aber hier nicht zuzutreffen.

Bei einer genaueren Betrachtung fällt auf daß der Blutspiegel des Neomycins nicht nur viel höher ist, sondern auch außergewöhnlich lange bestehen bleibt (Abb 14)

25 Stunden post inj war im Blutserum noch 1/6 der Anfangskonzentration vorhanden, während sich zur gleichen Zeit z. B. von Kanamycin oder Dihydrostreptomycin nur noch 1/2000 nachweisen ließ. Der extrem hohe und lang anhaltende Blutspiegel des Neomycins beruht sehr wahrscheinlich auf einer renalen Ausscheidungsstörung infolge einer toxischen Nierenschädigung. Aus der Literatur ist bekannt, daß bereits nach einer einmaligen Gabe von 100 mg Neomycin beim Meerschweinchen schwere Nierenschädigungen auftreten. Die hohe Neomycinkonzentration in den Innenohrflüssigkeiten muß in diesem Fall auf den extrem hohen Blutserumspiegel zurückgeführt werden und kann noch nicht als Ausdruck einer spezifischen Kumulationsneigung des Neomycins aufgefaßt werden. Dieser Befund bestätigt aber die aus zahlreichen Untersuchungen und klinischen Beobachtungen bekannte erheblich stärkere Otoloxizität des Neomycins, die jedoch hier wie in zahlreichen klinischen Fällen nur eine Folge der besonders ausgeprägten nephrotoxischen Wirkung darstellt.

TABELLE 2 Neomycinkonzentration nach subkutaner Injektion von 20 mg Neomycinsulfat/kg Meerschweinchen

Std. post. inj	Perilymphe	Serum	Herz	Leber	Gehirn
1	111 (± 60)	29 (± 13)	Spur (< 0.1)	—	—
5	45 (± 21)	3,5 (± 4.7)	—	—	—
18	20 (± 6.6)	< 0.1	—	—	—
25	10,6 (± 3.7)	< 0.1	—	—	—

γ Neomycin/ml (g Trockengewicht)

Um sich ein klareres Bild über die ototoxische Eigenschaft des Neomycins machen zu können, mußte der Einfluß einer Nierenschädigung ausgeschlossen werden. Hierzu war es notwendig, die Neomycindosis noch weiter bis auf 20 mg/kg, d. h., 1/10 der sonst bei den Streptomycinantibiotika üblichen Dosis, zu reduzieren. Bei dieser Dosierung lassen sich Neomycinblutspiegel erzielen, die praktisch denen einer gleich hohen Kanamycininjektion entsprechen. Eine verzögerte Ausscheidung als Zeichen einer renalen Intoxikation war jetzt nicht mehr zu beobachten. Trotzdem erreichte die Neomycinkonzentration in der Perilymphe noch eine überraschende Höhe wie wir sie bisher bei keinem anderen Antibiotikum gesehen haben. Sie betrug gut das 5-fache der Innenohrkonzentration, die sonst bei einer 10-fach höheren Dosierung mit Kanamycin erreicht wird und übertraf sogar den maximalen Neomycin Blutspiegel um mehr als das 3-fache (Tab. 2). In den übrigen Organen fand sich dagegen überhaupt kein Neomycin, bzw. die Neomycinkonzentration lag unter der Nachweisgrenze von 0.1 γ /g.

Für diese ausgeprägte Kumulation und Retention des Neomycins in der Perilymphe haben wir keine andere Erklärung als die Annahme einer substanzspezifischen Kumulationsneigung, deren Ursache möglicherweise auf einer membranblockierenden Wirkung beruht wie wir sie bereits bei Kanamycin diskutiert haben. Es liegt nahe die stärkere Haarzellschädigende Wirkung des Neomycins ausschließlich als einen Konzentrationseffekt zu deuten. Jedoch scheinen die Verhältnisse wie die Wechselwirkungen zwischen der Konzentration einerseits und der toxischen Schädigung auf der anderen Seite zeigten in Wirklichkeit komplizierter zu sein. Die hohe Konzentration bedingt zwar primär die Schädigung des Innenohrs, umgekehrt begünstigt aber die Schädigung wiederum eine verstärkte Anreicherung, so daß eine genaue Feststellung von Ursache und Folge kaum möglich ist.

VIII Untersuchungen zur Frage der Toxizitätsminderung

1. Das Verhalten der verschiedenen Antiothentatverbindungen des Kanamycins im Vergleich mit dem Sulfat

In Anbetracht der engen Beziehungen, die zwischen der Ototoxizität und der Konzentration der Streptomycinantibiotika im Innenohr zu bestehen

Abb. 15. Blutspiegel verschiedener Kanamycinverbindungen. (Alle Werte sind auf die Kanamycinbase bezogen.)

scheinen, mußte man sich fragen, ob nicht die geringere Toxizität, die vor allem den Pantothensäuren der Streptomycesantibiotika nachgesagt wird, möglicherweise auf einer niedrigeren Konzentration dieser Substanzen in den Innenohrflüssigkeiten beruht. Es wurden die Spiegel verschiedener Pantothensäureverbindungen, des Kanamycin Monopantothenats, des Kanamycin Di- und Tripanotothenats und des Kanamycinbase untersucht. Um vergleichbare, äquimolare Kanamycinmengen zu erhalten, war es wegen der unterschiedlichen Molekulargewichte dieser Substanzen erforderlich, die Dosis jeweils auf die Kanamycinbase zu beziehen.

Bereits eine Stunde nach der Injektion konnte man feststellen, daß sich das Monopantothenat gegenüber den Di- und Tripanotothenatverbindungen durch einen etwas niedrigeren Blutspiegel auszeichnet. Dieser Befund ließ sich allerdings statistisch infolge der geringen Versuchszahl noch nicht sichern (Abb. 15).

Durch die deutlich langsamere Ausscheidung der Di- und Tripanotothenate verglichen mit dem Monopantothenat vergrößerte sich die Differenz im weiteren Verlauf des Versuches. 5 Stunden post inj. als der Blutspiegel des Monopantothenates wieder auf 2% gesunken war der Blutspiegel der Di- und Tripanotothenate aber immerhin mit 8-9% noch gut 3 mal so hoch war wie der des Monopantothenates, ließ sich der Unterschied mit $p < 0,01$ statistisch sichern.

TABELLE 2 Neomycinkonzentration nach subkutaner Injektion von 95 mg Neomycinsulfat/kg Meerschweinchen

Std. post. Inf.	Perilymphe	Serum	Herk	Leber	Gehirn
1	111 (± 69)	29 (± 13)	Spur ($< 0,1$)	—	—
5	43 (± 21)	3,5 ($\pm 4,7$)	—	—	—
10	20 ($\pm 6,0$)	$< 0,1$	—	—	—
25	106 ($\pm 3,7$)	$< 0,1$	—	—	—

γ Neomycin/ml (g Trockengewicht)

Um sich ein klareres Bild über die ototoxische Eigenschaft des Neomycins machen zu können mußte der Einfluß einer Nierenschädigung ausgeschlossen werden. Hierzu war es notwendig, die Neomycindosis noch weiter bis auf 25 mg/kg, d. h. 1/10 der sonst bei den Streptomycinantibiotika üblichen Dosis, zu reduzieren. Bei dieser Dosierung lassen sich Neomycinblutspiegel erzielen, die praktisch denen einer gleich hohen Kanamycininjektion entsprechen. Eine verzögerte Ausscheidung als Zeichen einer renalen Intoxikation war jetzt nicht mehr zu beobachten. Trotzdem erreichte die Neomycinkonzentration in der Perilymphe noch eine überraschende Höhe, wie wir sie bisher bei keinem anderen Antibiotikum gesehen haben. Sie betrug gut das 5-fache der Innenohrkonzentration, die sonst bei einer 10-fach höheren Dosierung mit Kanamycin erreicht wird und übertraf sogar den maximalen Neomycin Blutspiegel um mehr als das 3-fache (Tab. 2). In den übrigen Organen fand sich dagegen überhaupt kein Neomycin, bzw. die Neomycinkonzentration lag unter der Nachweisgrenze von 0,1 γ/g .

Für diese ausgeprägte Kumulation und Retention des Neomycins in der Perilymphe haben wir keine andere Erklärung als die Annahme einer substanzspezifischen kumulationsneigung, deren Ursache möglicherweise auf einer membranblockierenden Wirkung beruht wie wir sie bereits bei Kanamycin diskutiert haben. Es liegt nahe die stärkere haarzellschädigende Wirkung des Neomycins ausschließlich als einen Konzentrationseffekt zu deuten. Jedoch scheinen die Verhältnisse wie die Wechselwirkungen zwischen der Konzentration einerseits und der toxischen Schädigung auf der anderen Seite zeigten, in Wirklichkeit komplizierter zu sein. Die hohe Konzentration bedingt zwar primär die Schädigung des Innenohres, umgekehrt begünstigt aber die Schädigung wiederum eine verstärkte Anreicherung, so daß eine genaue Feststellung von Ursache und Folge kaum möglich ist.

VIII Untersuchungen zur Frage der Toxizitätsminderung

1 Das Verhalten der verschiedenen Tautollenatverbindungen des Kanamycins im Vergleich mit dem Sulfat

In Anbetracht der engen Beziehungen die zwischen der Ototoxizität und der Konzentration der Streptomycinantibiotika im Innenohr zu bestehen

kanamycinsalze an der Abnahme der Mikrophonpotentiale und fand ebenfalls unter Kanamycinmonopantothemat keine Schädigung des Gehörs, während die Di- und Tripanthemat einen ähnlichen Hörabfall hervorriefen wie Kanamycinsulfat. Er teilte uns kürzlich mit, daß er unserer Ansicht zu stimmt und ebenfalls die Ursache für die verschieden starke Toxizität als eine Konzentrationsfrage ansieht.

Größere Schwierigkeiten bereitet jedoch ein Vergleich der Pantothematgruppe mit dem Sulfatsalz. Die Blutkonzentrationen der Kanamycin-Pantothemat und des Kanamycinsulfates wiesen zwar 1 Stunde nach der Injektion Unterschiede auf, die insofern Beachtung verdienen, da sie eine überraschende Übereinstimmung mit den Ergebnissen Tybergheins erkennen lassen (Abb 15). Es zeigt sich, daß die Substanzen mit der größten Toxizität wie die Sulfat- und Dipantothematverbindungen auch den höchsten Blutspiegel erreichten, gefolgt von dem etwas weniger giftigen Tripanthemat, während Kanamycinmonopantothemat den eindeutig niedrigsten Blutspiegel aufwies. Die Reihenfolge ihrer Konzentration würde also genau ihrer toxischen Wirksamkeit entsprechen. So interessant diese Feststellung auch sein mag, so muß doch zu Bedenken gegeben werden, daß die relativ geringen Konzentrationsunterschiede in Anbetracht der großen Streuung und zu niedrigen Versuchszahl statistisch noch nicht zu sichern waren.

Für Mäcker und Mitarbeiter waren diese Befunde von besonderem Interesse, da sie der entgiftenden Wirkung der Pantothemat große praktische Bedeutung beimessen. Sie reproduzierten die gleichen Versuche dasuffin nochmals an Meeresschnecken und Ratten. Dabei ergaben sich ebenfalls eine Stunde post inj für Kanamycinsulfat die höchsten Blutkonzentrationen, während die Pantothematsalze bis zu 15% niedriger lagen. Eine statistisch signifikante Differenz gegenüber Kanamycinsulfat konnte allerdings hier nur für Kanamycintripantothemat ermittelt werden.

2 bzw. 5 Stunden nach einer Injektion war der Blutspiegel, wie auch Mäcker und Mitarbeiter übereinstimmend mit unseren Versuchen zeigen konnten, vor allem für Kanamycinsulfat, das offensichtlich schneller als die größeren Pantothematmoleküle eliminiert wird, bereits erheblich gesunken. Der unterschiedliche Konzentrationszeitverlauf des Sulfates im Vergleich zu den Pantothemat führt im weiteren Verlauf zu einer Änderung und Umkehr des Sulfat-Pantothematverhältnisses.

Für das Innenohr läßt sich anhand der Konzentrationskurven auf Abb. 16 sagen, daß bei gleich hoher äquimolarer Dosierung die Di- und Tripanthematverbindungen einen höheren Spiegel aufweisen als das Kanamycinsulfat, während die Konzentration des Kanamycinmonopantothemates der des Kanamycinsulfates weitgehend entspricht. Wenn man unterstellt, daß Kanamycin Di- und Tripanthemat trotz höherer Innenohrkonzentration angeblich nicht toxischer sein soll, könnte man hieraus auf einen Effekt tritt allerdings bei gleicher Dosierung nicht in Erscheinung, da

Abb 16 Perilymphspiegel verschiedener Kanamycinanaloge (Alle Werte beziehen sich auf die Kanamycin Base)

Ähnlich wie im Blut verhielten sich die Kanamycinpantothenate auch in den Innenohrflüssigkeiten (Abb 16)

In den ersten Stunden nach der Infektion ließen die Innenohrkonzentrationen der verschiedenen Substanzen zunächst nur geringe Unterschiede erkennen. Im weiteren Verlauf wurden die Differenzen immer deutlicher. 5 Stunden nach der Infektion zeigte es sich auch hier, daß Kanamycinmonopantothenat von allen Pantothenaten die weitestgehend geringste Konzentration aufweist. Der Gehalt der Innenohrflüssigkeiten an Kanamycinmonopantothenat war mit 10 γ /ml Perilymphe signifikant niedriger ($p < 0.01$) als an Tripantothenat mit 38 γ /ml. Der Unterschied zum Dipantothenat mit 25 γ /ml ließ sich nicht sichern ($p > 0.1$). Zwischen dem Verhalten der Kanamycinpantothenate im Blut und in den Innenohrflüssigkeiten scheint eine Beziehung zu bestehen. Wahrscheinlich ist die niedrigere Blutkonzentration des Monopantothenates für die geringere Innenohrkonzentration und somit für die schwächere ototoxische Wirkung dieser Verbindung ursächlich verantwortlich zu machen.

Tybergheln bestimmte die unterschiedliche Toxizität der einzelnen Kanamycinpantothenate.

KONZENTRATION VON STREPTOMYCINSULFAT UND STREPTOMYCINSULFAT-OXOTRIN IN

Abb. 17 b. Vergleich der Streptomycinspiegel mit und ohne Oxotrin.

er durch die höhere Konzentration der Pantothenatverbindungen im Innenohr wieder aufgehoben wird

Die Perilymphspiegel der Kanamycinpantothenatverbindungen weisen zwar für sich betrachtet eine gute Relation zu den Toxizitätsuntersuchungen Tybergheins auf. Sie sind nicht nur eine weitere Bestätigung, sondern geben uns auch eine Erklärung dafür, warum offensichtlich Kanamycinmonopantothenat von allen Kanamycinpantothenatverbindungen die geringste Toxizität besitzt. Kanamycinmonopantothenat ist, genau gesagt, nicht weniger ototoxisch als die Tri- und Dipantothenatverbindungen, sondern kommt nur in einer geringen Konzentration im Innenohr vor.

Nicht hiermit in Einklang zu bringen ist jedoch der ebenfalls relativ niedrige dem Kanamycinmonopantothenat entsprechende Innenohrspiegel des Kanamycinsulfats. Sowohl Tyberghein als auch J. P. Brun (mündliche Mitteilung) sahen bei elektrophysiologischen und histologischen Untersuchungen eine signifikant geringere Toxizität des Kanamycinmonopantothenats im Vergleich zum Sulfatsalz. Dagegen kamen kürzlich Merkle, Platzig und Heidel (1968) aufgrund elektrophysiologischer und histologischer Untersuchungen an der Katze zu dem Schluß, daß Kanamycinpantothenat genauso toxisch ist wie Kanamycinsulfat, während sich die Kanamycin-Di- und Tripantothenate als stärker toxisch erwiesen. Diese letzteren Ergebnisse zeigen interessanterweise genau eine Parallele zu den Konzentrationsverhältnissen dieser Kanamycinverbindungen im Innenohr wie sie Abb. 16 darstellt.

Eine Erklärung für die zum Teil abweichenden Befunde der verschiedenen Untersucher ist darin zu sehen, daß die Schutzwirkung bzw. die Toleranzverbesserung durch Pantothenensäure nach Schatzung, Müsebeck im günstigsten Fall 30% ausmacht. Vielleicht ist gerade in diesem relativ geringen, und darum auch verständlicherweise nur schwer zu sichernden Toxizitätsunterschied zwischen der Sulfat- und Pantothenatverbindung die Ursache zu suchen, warum die Schutzwirkung der Pantothenensäure nur von einigen Untersuchern beobachtet, von anderen aber nicht festgestellt werden konnte und abgelehnt wird. Man möchte hier der Ansicht Müsebecks zustimmen, daß die Ursache für die unterschiedlichen Ergebnisse im Tierexperiment in der bewußt zur Erzielung schwerer toxischer Schädigungen angewandten, viel höheren Dosierung zu suchen ist, so daß die geringe toxizitätsmindernde Wirkung der Pantothenate überlagert wird und nicht mehr in Erscheinung tritt.

2. Hat Ozothin® einen Einfluss auf die Streptomycisantibiotika?

In jüngster Zeit wurde durch zahlreiche Publikationen der Freiburger Hals-, Nasen- u. Ohrenklinik das Interesse vor allem auf Ozothin (s. Seite 48) gelenkt, daß u. a. als Lösungsmittel für Antibiotika Anwendung findet. Holz und Mitarbeiter machten die Beobachtung, daß Ozothin die toxische Wirkung nicht nur des Streptomycins, sondern auch der übrigen Aminoglykosidantibiotika, praktisch vollständig verhindern soll. Dieser Ef-

TABELLE 3 Streptomycinkonzentration in $\mu\text{g/g}$ 1 bzw. 5 Stunden nach subkutaner Injektion von 250 mg Streptomycin/kg Meerschweinchen und 250 mg in O-othlin gelöstem Streptomycin/kg

		Herz		Leber		Gehirn	
1 Std. post inj.	Streptomycin	5,3	$\pm 0,3$	0,39	$\pm 0,27$	0,32	$\pm 0,23$
	Streptomycin						
	+ Oothlin	1,3	$\pm 0,5$	0,16	$\pm 0,03$	0,17	$\pm 0,037$
5 Std. post inj.	Streptomycin	0,3	$\pm 0,07$	0,013	$\pm 0,012$	0,023	$\pm 0,012$
	Streptomycin						
	+ Oothlin	0,04	$\pm 0,011$	0		■	

keine cochleotoxischen Schäden mehr fanden. Dagegen vermag Oothlin unter den gleichen Versuchsbedingungen, wie Lange, der der Arbeitsgruppe um Holz angehört, unlängst berichtete, die im Allgemeinen wesentlich stärkeren vestibulären Störungen und morphologisch nachweisbare Schäden am peripheren Gleichgewichtsapparat nicht zu verhindern. Es zeigte sich kein Unterschied im Vergleich zu den Tieren, die nur SM erhalten hatten.

Dieser Befund überrascht nicht weiter sondern bestätigt vielmehr den Verdacht, daß die Oothlinwirkung auf einer Herabsetzung der Streptomycinkonzentration beruht. Da die toxische Schwelle für das Hörorgan bei Streptomycin bekanntlich wesentlich höher liegt als die des Gleichgewichtsapparates, genügt wahrscheinlich die durch Oothlin hervorgerufene Konzentrationsminderung um Hörschäden zu vermeiden. Sie reicht aber offensichtlich nicht aus, um auch Gleichgewichtsstörungen zu verhindern. Die niedrigere toxische Schwelle für das Gleichgewichtsorgan erfordert, wenn man vestibuläre Schäden ausschließen will, eine noch stärkere Herabsetzung des Streptomycinspiegels. Hierzu genügt Oothlin allein offenbar nicht.

Die Tatsache, dass Oothlin bei etwas stärker wirkenden Substanzen, wie z. B. Kanamycin, ebenfalls keinen Schutzeffekt mehr besitzt, könnte auf die gleiche Weise erklärt werden. Tybergheim kam nach eingehenden Untersuchungen zu der Feststellung, dass Oothlin nicht in der Lage ist, die Abnahme der Mikrophonpotentiale zu verhindern. Er glaubt sogar unter Oothlin eher stärkere Schädigungen gesehen zu haben.

Zu dem gleichen Ergebnis gelangte kürzlich auch J. P. Brun, der bei quantitativen, histologischen Untersuchungen an Cytocochleogrammen unter Kanamycininfekt, ohne und mit Oothlin, die gleichen Haarzellschädigungen sah.

Trotz dieser negativen Beurteilungen des Oothlins kann man, im Hinblick auf die nachgewiesene Konzentrationsverminderung der toxischen Antibiotika sagen, Oothlin vermag, zwar in geringem Umfang, ototoxische Schäden zu verhüten.

Es ist aber nicht in der Lage, Streptomycin zu entgiften. Eine Entgiftung

fekt soll auch dann noch eintreten, wenn Ozothin und das Antibiotikum nicht in einer gemeinsamen Lösung injiziert, sondern getrennt verabreicht werden. Erstaunlicherweise tritt die Schutzwirkung des Ozothins angeblich nur dann ein, wenn Ozothin gleichzeitig oder vorher mit dem Antibiotikum verabfolgt wird. Sie bleibt dagegen aus, wenn Ozothin erst eine oder wenige Minuten später injiziert wird. Da dieser günstige Ozothineffekt nur von Holz und Mitarbeitern bisher beschrieben wurde, von allen anderen Untersuchern aber nicht bestätigt werden konnte, erschienen weitere Untersuchungen angebracht. Hier geht es vor allem darum zu klären, worauf diese angeblich Toxizitätsmindernde Eigenschaft des Ozothins beruht. Die Frage, die man sich auch hier zuerst stellen muss, lautet: Ist die Ozothinwirkung lediglich auf einen Konzentrationseffekt zurückzuführen, oder handelt es sich um eine echte Entgiftung?

Betrachten wir zunächst den Konzentrationszeitverlauf des Streptomycins ohne und mit Ozothin im Blutserum und in den Innenohrflüssigkeiten wie ihn Cada, Brun und Stupp bei ihren Untersuchungen am Meerschweinchen fanden. Abb. 17a und b zeigt die Blut- und Perilymphspiegel des Streptomycins und im Vergleich dazu die um 20–25% niedrigeren Spiegel bei Ozothinzusatz.

Wie schon bei den Jantothennatverbindungen so fällt auch hier auf, daß die Verhältnisse im Blut und in den Innenohrflüssigkeiten sehr ähnlich sind. Man könnte hieraus auf eine Beziehung zwischen der Blut- und Innenohrkonzentration schließen.

Zu dem gleichen Ergebnis kamen auch Mückler und Mitarbeiter. Sie konnten ebenfalls unter Ozothin eine signifikante Herabsetzung des Blutspiegels feststellen. Während Ratten normalerweise 1 Stunde nach der Injektion von Streptomycin einen Blutserumspiegel von durchschnittlich 643 μg Streptomycin/ml aufwiesen, lag dieser Wert unter Ozothin bei 354 $\mu\text{g}/\text{ml}$, also um annähernd 50% niedriger. Dieser Effekt war wie sich auch bei den Untersuchungen Mücklers zeigte, bei Meerschweinchen mit ungefähr 20% nicht so ausgeprägt. Ließ sich aber noch statistisch sichern. Hoffmann und Holz teilten erst kürzlich mit, daß auch sie unter Ozothin eine Verminderung des Blutspiegels feststellen mußten.

Am auffälligsten zeigt sich der Einfluß des Ozothins an den Organen, die, wie ein Vergleich der Gewebesspiegel ergibt, viel weniger Streptomycin aufnehmen als bei den ausschließlich mit Streptomycin behandelten Tieren. Wie aus der Tabelle 3 zu ersehen ist, vermindert Ozothin den Streptomycingehalt in der Leber um mehr als 50%, im Herz und Gehirn sogar um über 70%. 5 Stunden post inj. war in den Organen der Ozothintiere praktisch kein Streptomycin mehr nachweisbar.

Um sich einen genaueren Aufschluß über den Ozothineffekt zu verschaffen, müßten zunächst einmal vergleichbare Bedingungen d.h. gleiche Konzentrationsverhältnisse im Blut und Gewebe bei den Ozothin- und Kontrolltieren hergestellt werden. In Anbetracht des niedrigeren Streptomycingehaltes unter Ozothin ist es nicht verwunderlich, wenn Holz und Mitarbeiter

Die Tatsache, dass Ozothin bei etwas stärker wirkenden Substanzen, wie z. B. Kanamycin, ebenfalls keinen Schutzeffekt mehr besitzt, könnte auf die gleiche Weise erklärt werden. Tybergheim kam nach eingehenden Untersuchungen zu der Feststellung, dass Ozothin nicht in der Lage ist, die Abnahme der Mikrophonpotentiale zu verhindern. Er glaubt sogar unter Ozothin eher stärkere Schädigungen geschehen zu haben.

Zu dem gleichen Ergebnis gelangte kürzlich auch J. P. Brun, der bei quantitativen, histologischen Untersuchungen an Cytocochleogrammen unter Kanamycininfusion, ohne und mit Ozothin, die gleichen Haarzellschädigungen sah.

Trotz diese negativen Beurteilungen des Ozothins kann man, im Hinblick auf die nachgewiesene Konzentrationsverminderung der toxischen Antibiotika sagen, Ozothin vermag, zwar in geringem Umfang, ototoxische Schäden zu verhüten.

Es ist aber nicht in der Lage, Streptomycin zu entgiften. Eine Entgiftung

Abb 18 Vergleich der Blut und Perilymphkonzentrationen bei niedrigem Kanamycin (25 mg/kg) und 10fach höherer Penicillin-dosis (250 mg/kg)

im strengen Sinne liegt erst vor wenn es gelingt bei gleich hohem Antibiotikaspiegel die unter Erhaltung der vollen therapeutischen Wirkung, die toxische Eigenschaft dieser Substanzen zu vermindern. Diese Anforderung scheint auch Ozothin, soweit man dieses nach den Antibiotikakonzentrationen beurteilen kann, nicht zu erfüllen. Ein derartiger Effekt wie wir ihn bei Ozothin sehen läßt sich wahrscheinlich ebenso durch eine entsprechend niedrigere Streptomycindosis erzielen.

In diesem Zusammenhang muß hier festgestellt werden daß Ozothin die antibiotische Aktivität der Streptomycesantibiotika auf Bakterienkulturen in vitro nicht beeinflußt. Es bedeutet aber nicht viel wenn Mückter darauf verweist daß eine Verminderung der therapeutischen bzw. antibiotischen Wirksamkeit durch Ozothin experimentell an chronisch tuberkuloseinfizierten Tieren ebenfalls nicht beobachtet werden konnte. Man darf hierbei nicht übersehen daß es sich in diesen tierexperimentellen Fällen um relativ grobe Untersuchungsmethoden mit großen Fehlerbreiten handelt. Die Auswirkung einer 20-25% igen Konzentrations- oder Dosisverminderung kann mit dieser Methode überhaupt nicht erfaßt werden. Daß eine Konzentrationsverminderung, wie sie nachweislich vorliegt, sei es auch nur um 20% für die Therapie wie Mückter meinte belanglos sein soll ist schwer einzusehen. Wenn dies der Fall wäre müßte man zu Recht fragen warum wird dann nicht einfach statt wie bisher üblich 1 g Streptomycin nur 0,8 verabreicht. Da sich die therapeutische Dosierung, wie wir sehen bereits im Bereich der toxischen Schwelle bewegt würde möglicherweise schon diese Reduzierung der Dosis ausreichen, um den kritischen toxischen Schwellenbereich zu vermeiden.

Wie soll man die Wirkungsweise des Ozoithins erklären? Man neigt zu der Auffassung, dass ätherische Öle, wozu auch Ozoithin zu rechnen ist, ähnlich wie andere Öle die Resorption des Antibiotikums an der Injektionsstelle verzögern, also eine Depotwirkung ausüben.

In diesem Fall müßte man aber einen anderen Verlauf des Blutspiegels erwarten, als ihn Abb. 17 zeigt. Die Blutkonzentrationskurve läge zwar niedriger würde dafür aber breiter d. h., zeitlich protrahierter verlaufen. Der Streptomycinspiegel des Blutes unter Ozoithin überschneidet jedoch zu keinem Zeitpunkt die normale Streptomycinkonzentrationskurve, sondern bleibt stets unter dieser. Das bedeutet, ein Teil des verabfolgten Streptomycins gelangt nicht in die Blutbahn. Über den Verbleib und das Schicksal des restlichen Streptomycins weiß man bis heute nichts.

Schwieriger ist die Deutung der unverhältnismäßig niedrigen Organkonzentration. Die Annahme liegt nahe, daß die membranabdichtende Wirkung der ätherischen Öle, die schon ohnehin erschwerte Aufnahme des Streptomycins in die Zellen der Organe verhindert. Ein Membraneffekt wäre ebenfalls zur Erklärung der behinderten Resorption am Injektionsort in Betracht zu ziehen. Auch im Innenohr könnte auf diese Weise ein Eindringen des Streptomycins von der Perilymphe in die Sinnesepithelien erschwert sein und dadurch u. U. sogar eine Schutzwirkung erklärt werden. Für diese mehr spekulativen Annahmen gibt es jedoch bis jetzt keine Beweise. Erwiesen ist nur, daß Ozoithin den Antibiotikaspiegel herabsetzt und in geringem Umfang toxische Hörschäden durch Streptomycinsantibiotika zu verhindern vermag.

IX. Die Konzentrationen nicht ototoxischer Antibiotika, des Polymyxins, Tetracyclins und Penicillins im Innenohr und anderen Organen

Auf Grund dieser Befunde sollte man nun erwarten, daß sich alle Stoffe mit ähnlichen Permeationseigenschaften wie die Aminoglykosidantibiotika im Innenohr in gleicher Weise verhalten. Demnach müßten sämtliche nicht resorbierbaren Substanzen in den Innenohrräumen eine relative Anreicherung erfahren. Bei Inulin fanden wir diese Analogie zwar bestätigt. Mückter wies aber auf eine andere Antibiotikagruppe, die Polymyxine hin, die diese Anforderungen offensichtlich nicht erfüllen. Obwohl die Polymyxine wie das Colistin (Polymyxin E) sehr toxisch sind und außerdem die Eigenschaft besitzen, nicht resorbierbar zu sein, rufen sie bemerkenswerterweise keine ototoxischen Erscheinungen, sondern nur allgemeine neurotoxische Symptome hervor. Das Verhalten des Colistins wurde von Mückter als Beweis dafür angeführt, daß unsere Auffassung nicht zutrifft und die schlechte Resorbierbarkeit offenbar für die Kumulation im Innenohr und für die toxische Wirkung ohne Bedeutung ist. Diese Tatsache schien vielmehr die bis heute vorherrschende Hypothese von einer spezifischen

Abb 18 Vergleich der Blut und Perilymphkonzentrationen bei niedriger Kanamycin (25 mg/kg) und 10fach höherer Penicillin Dosis (250 mg/kg)

Im strengen Sinne liegt erst vor wenn es gelingt bei gleich hohem Antibiotikaspiegel d. h. unter Erhaltung der vollen therapeutischen Wirkung, die toxische Eigenschaft dieser Substanzen zu vermindern. Diese Anforderung scheint auch Ozothin soweit man dieses nach den Antibiotikakonzentrationen beurteilen kann, nicht zu erfüllen. Ein derartiger Effekt wie wir ihn bei Ozothin sehen läßt sich wahrscheinlich ebenso durch eine entsprechend niedrigere Streptomycindosis erzielen.

In diesem Zusammenhang muß hier festgestellt werden daß Ozothin die antibiotische Aktivität der Streptomycinesantibiotika auf Bakterienkulturen in vitro nicht beeinflußt. Es bedeutet aber nicht viel wenn Mückler darauf verweist daß eine Verminderung der therapeutischen bzw. antibiotischen Wirksamkeit durch Ozothin experimentell an chronisch tuberkuloseinfizierten Tieren ebenfalls nicht beobachtet werden konnte. Man darf hierbei nicht übersehen, daß es sich in diesen Tierexperimentellen Fällen um relativ grobe Untersuchungsmethoden mit großen Fehlerbreiten handelt. Die Auswirkung einer 20-25% igen Konzentrations- oder Dosisverminderung kann mit dieser Methode überhaupt nicht erfaßt werden. Daß eine Konzentrationsverminderung, wie sie nachweislich vorliegt sei es auch nur um 20% für die Therapie, wie Mückler meinte belanglos sein soll, ist schwer einzusehen. Wenn dies der Fall wäre müßte man zu Recht fragen warum wird dann nicht einfach statt wie bisher üblich 1 g Streptomycin nur 0,8 verabreicht. Da sich die therapeutische Dosierung, wie wir sehen, bereits im Bereich der toxischen Schwelle bewegt würde möglicherweise schon diese Reduzierung der Dosis ausreichen, um den kritischen toxischen Schwellenbereich zu vermeiden.

1963 Fellers und Lindquist, 1964 Zimmermann und Werther 1964 Wegienka und Weller, 1964 Sulkowski und Hasek, 1964 Mavromatis, 1965) auch zu Innenohrschädigungen führen würden, wenn sie in das Innenohr eindringen könnten. Für die Praxis bedeutet dieser Befund, daß Polymyxine und Tetracycline für eine parenterale Behandlung entzündlich bakterieller Innenohrerkrankungen wenig geeignet sind, dafür aber andererseits den großen Vorzug besitzen, keine ototoxische Nebenwirkung zu haben. Das schließt jedoch nicht aus, daß bei ihrer lokalen Anwendung vor allem bei einer offenen Paukenhöhle und großen Radikal- oder Fensterungsböhlen, wo sie in unmittelbare Nähe des Innenohres gelangen, durch Diffusion toxisch wirksame Antibiotikamengen in das Innenohr gelangen und Schädigungen hervorrufen können. Für die Polymyxine und möglicherweise auch für die Tetracycline gilt grundsätzlich das gleiche wie für die toxischen Streptomycesantibiotika. Voraussetzung für ihre Ototoxizität ist, daß sie in einer toxisch wirksamen Konzentration den Schädigungsort erreichen. So konnten Kolde, Hata und Hando (1966) z. B. Tierexperimente zeigen, daß sogar Chloramphenicol, wenn es in die Paukenhöhle unmittelbar vor das runde Fenster appliziert wird, ähnliche Innenohrschädigungen hervorruft wie Kanamycin oder Dihydrostreptomycin.

Die vorliegenden Befunde, das darf man zusammenfassend sagen, machen eine Korrektur der bisherigen Vorstellungen von der spezifischen Sensibilität des Innenohres gegenüber den Aminoglykosidantibiotika erforderlich. „Spezifisch“ kann wahrscheinlich nur der kumulationsprozeß im Innenohr genannt werden. Wir kennen keine anderen Pharmaka, die in einer solchen hohen Konzentration im Innenohr vorkommen wie die Antibiotika der Oligosaccharidgruppe. Selbst Penicillin, das für seine gute Liquorgängigkeit bekannt ist, fand sich in den Innenohrflüssigkeiten nur in vergleichsweise geringen Konzentrationen, die niemals den Blutspiegel übertrafen (Abb. 18). Charakteristisch für die Streptomycesantibiotika ist, daß sie selbst bei niedrigster nicht toxischer Dosierung, wie die Abb. 18 zeigt, im Innenohr einen höheren Spiegel aufweisen können als im Blut.

Die vorliegenden Befunde sollen zeigen, daß bei der Untersuchung der Ototoxikosen genau wie bei jeder anderen Intoxikation die Frage nach der Konzentration der toxischen Substanzen am Anfang aller Überlegungen stehen sollte. Sie alleine vermag schon vieles zu erklären, das gilt sowohl in therapeutischer Hinsicht als auch für die Giftwirkung und nicht zuletzt für die Bemühungen um eine Entgiftung. Das Wort Pharmakon hat in der griechischen Sprache einen doppelten Sinn. Es bedeutet Arznei und Gift. Paracelsus sagte der einzige Unterschied, ob ein Ding ein Gift sei oder nicht, liege in der Dosis. Diese alte Erkenntnis ist gerade im Hinblick auf die Streptomycesantibiotika von Bedeutung, weil hier die therapeutisch und toxisch Dosis dicht nebeneinander liegen und eine Abgrenzung zwischen Arznei und Gift besonders schwierig ist.

Sensibilität des Innenohres gegenüber den Aminoglykosidantibiotika zu stützen

Die Frage warum Colistin nur neuro- nicht aber ototoxisch ist stellt wie eine Untersuchung der Colistinspiegel ergab, ausschließlich ein Konzentrationsproblem dar (Tab. 4)

Es zeigte sich daß die Polymyxine eine wesentliche Voraussetzung für eine Kumulation im Innenohr und für eine ototoxische Wirkung nicht erfüllen. Wie aus der Tabelle hervorgeht kann Colistin offensichtlich nicht vom Blut in den Perilymphraum übertreten ebensowenig wie es die Blut Liquorschranke zu passieren vermag.

Eine ähnliche Erscheinung konnte bei den Tetracyclinen festgestellt werden (Tab. 5). Auch sie können bekanntlich die Blut Liquorschranke nicht überschreiten. Genausowenig sind sie in der Lage wie die Tabelle zeigt die Blut Lymphschranke zum Innenohr zu überwinden.

Dagegen kommen Tetracycline in allen anderen Organen sogar in relativ hohen Konzentrationen vor. Über die Blut Liquor bzw. Blut Lymphschranke bestehen noch keine konkreteren Vorstellungen. Es wird auf Grund der unterschiedlichen Zusammensetzung des Liquors und der Innenohrlymphe angenommen daß es sich um zwei verschiedene Schranken handelt. Sicher kann man aber sagen daß die Molekülgröße alleine nicht zur Erklärung ausreicht da wesentlich größere Moleküle wie Inulin und Albumin ohne Schwierigkeiten in das Innenohr gelangen.

Es wäre durchaus vorstellbar daß die Tetracycline ähnlich wie sie in der Niere Zerstörungen der Tubuli hervorrufen (Cross, 1963; Frimpter

TABELLE 5 *Tetracyclin-konzentration nach einer einmaligen subkutanen Injektion von 100 mg Tetracyclin HCl/kg*

Stunden post Inj	Blutserum (μ /ml)	Herz (μ /g)	Leber (μ /g)	Gehirn (μ /g)	Perilymphe (μ /ml)
1	11.0 \pm 1.75	3. — 0.2	3.7 \pm 0.6	—	—
5	1.7 \pm 1.65	2.05 \pm 0.37	1.0 \pm 0.15	—	—

Konzentrationszeitverlauf, insbesondere auf den Innenohrspiegel der Aminoglykosidantibiotika haben. Aufgrund dieser Untersuchungen muß man annehmen, daß der Schutzeffekt des Oxithins wahrscheinlich auf der signifikanten Abnahme der Antibiotikakonzentration sowohl im Serum als auch im Innenohr und anderen Organen beruht. Die unterschiedliche Toxizität der einzelnen Pantothenat- und Sulfatverbindungen der Oligomycosanibiotika läßt sich wahrscheinlich ebenfalls auf ihre verschieden hohen Konzentrationen in der Innenohrlymphe zurückführen. Demnach scheint es sich nicht um eine echte Entgiftung, sondern lediglich um eine Konzentrations- bzw. Wirkungsminderung der toxischen Antibiotika zu handeln.

Diese Befunde machen eine Korrektur der bisherigen Vorstellungen über die spezifische Sensibilität des Innenohres erforderlich. „Spezifisch“ kann nur der charakteristische Kumulationsprozess der Aminoglykosidantibiotika im Innenohr genannt werden. An der Darmmucosa der Ratte läßt sich demonstrieren, daß auch hier wenn die toxischen Substanzen nur in einer entsprechend hohen Konzentration einwirken, ein histologisch sehr ähnliches Schädigungsbild der oberflächlichen Epithelschicht hervorgerufen wird, wie es von der Niere und dem Innenohr her bekannt ist. Sowohl die spezifisch-ototoxische Wirkung als auch die „Entgiftungsversuche“ der Aminoglykosidantibiotika können im wesentlichen als Konzentrationsselektio erklärt werden.

D ZUSAMMENFASSUNG

Keine der zahlreichen Theorien über die toxische Wirkungsweise der Aminoglykosidantibiotika vermag zu erklären, warum ausschließlich das Innenohr und die Niere geschädigt werden, während alle anderen Organe verschont bleiben. Man begnügte sich mit der Annahme, daß die Zellen des Innenohres eine spezifische Sensibilität gegenüber diesen Substanzen besitzen. Diese wenig befriedigende Hypothese war Anlaß, nach weiteren Ursachen zu forschen.

Eine Untersuchung der Verteilung und des Konzentrations-Zeit-Verlaufs der toxischen Streptomycosanibiotika beim Meerschweinchen brachte folgende Ergebnisse:

Alle Antibiotika der Aminoglykosidgruppe, sowohl Streptomycin und Dihydrostreptomycin als auch Kanamycin und Neomycin, werden in der Perilymphe und Endolymphe des Innenohres angereichert und retiniert. Ihre Konzentration im Innenohr und in der Niere übertrifft alle anderen Organe und sogar den Blutspiegel um ein Vielfaches. Je toxischer die Substanzen sind, umso ausgeprägter ist auch ihre Kumulation in der Innenohrlymphe. Offensichtlich besteht eine Relation zwischen der Konzentration und der Otokarzinogenität der verschiedenen Aminoglykosidantibiotika.

Schon in niedriger, nicht toxischer Dosierung erreichen die Antibiotika der Aminoglykosidgruppe einen relativ hohen Innenohrspiegel. Die Ursache hierfür ist wahrscheinlich in einer erschwerten Elimination und Retention der praktisch nicht resorbierbaren Substanzen dieser Antibiotikagruppe in den Innenohrräumen zu sehen. Eine vergleichbare Kumulation fand sich auch bei Inulin, das hinsichtlich seiner Verteilung im Organismus ähnliche pharmakologische Eigenschaften aufweist wie die toxischen Streptomycosanibiotika. Darüber hinaus kommt es mit Überschreiten der toxischen Schwelle noch zu einer weiteren unverhältnismäßig starken Zunahme der Innenohrkonzentration der Aminoglykosidantibiotika. Dieser letzte Vorgang, den man im Gegensatz zur normalen Kumulation als toxisch bedingten Kumulationsprozess bezeichnen kann, ist wahrscheinlich auf eine Störung der Membranpermeabilität zurückzuführen.

Andere Antibiotika, wie Penicillin, erreichen vergleichsweise nur einen minimalen Innenohrspiegel, während Tetracyclin und Chloramphenicol überhaupt nicht in das Innenohr einzudringen vermögen und darum auch nicht toxisch wirken können.

In diesem Zusammenhang wurde weiterhin die Frage zu klären versucht, ob Substanzen wie Lanthansäure oder Ozthion, die angeblich die Toxizität der Streptomycosanibiotika herabsetzen sollen, einen Einfluß auf den

Konzentrationszeitverlauf insbesondere auf den Innenohrspiegel der Aminoglykosidantibiotika haben. Aufgrund dieser Untersuchungen muß man annehmen, daß der Schutzeffekt des Oxothins wahrscheinlich auf der signifikanten Abnahme der Antibiotikakonzentration sowohl im Serum als auch im Innenohr und anderen Organen beruht. Die unterschiedliche Toxizität der einzelnen Pantothensäure- und Sulfatverbindungen der Oligomycosanantibiotika läßt sich wahrscheinlich ebenfalls auf ihre verschieden hohen Konzentrationen in der Innenohrlymphe zurückführen. Demnach scheint es sich nicht um eine echte Entgiftung, sondern lediglich um eine Konzentrations- bzw. Wirkungsaminderung der toxischen Antibiotika zu handeln.

Diese Befunde machen eine Korrektur der bisherigen Vorstellungen über die spezifische Sensibilität des Innenohres erforderlich. „Spezifisch“ kann nur der charakteristische Kumulationsprozess der Aminoglykosidantibiotika im Innenohr genannt werden. An der Darmmucosa der Ratte läßt sich demonstrieren, daß auch hier wenn die toxischen Substanzen nur in einer entsprechend hohen Konzentration einwirken, ein histologisch sehr ähnliches Schädigungsabild der oberflächlichen Epithelschicht hervorgerufen wird, wie es von der Niere und dem Innenohr her bekannt ist. Sowohl die spezifisch-ototoxische Wirkung als auch die „Entgiftungs-Versuche“ der Aminoglykosidantibiotika können im wesentlichen als Konzentrationsselekt erklärt werden.

E SUMMARY

None of the many theories on the toxic mode of action of the amino-glycoside antibiotics can account for the injuries done solely to both the inner ear and the kidney while all other organs remain unaffected. The mere assumption, that the cells of the inner ear show a specific sensitivity towards these substances, seemed to be a sufficient answer. However this rather unsatisfactory hypothesis gave rise to search for additional causes.

Following are the results obtained from a study on the distribution and the time of concentration of the toxic streptomycetes antibiotics in the guinea pig.

All antibiotics belonging to the group of amino-glycosides, including streptomycin and dihydrostreptomycin as well as kanamycin and neomycin, are concentrated and retained in the inner ear fluids. Their concentration both in the inner ear and the kidney exceeds that of all other organs, even of the blood level, many times over. The higher the toxicity of the substances, the more intense is their accumulation in the inner ear fluid.

Evidently there exists a relation between the concentration and the ototoxicity of the different amino-glycoside antibiotics.

Even a small and non toxic dose of the antibiotics of the amino-glycoside group will suffice to reach a relatively high level in the inner ear. The reason for this may be looked for in a complicated elimination and retention of the practically non absorbable substances of this particular group of antibiotics in the inner ear spaces. Also a comparable accumulation could be observed when administering inulin which with respect to its distribution in the guinea pig showed similar pharmacological properties like the toxic streptomycetes antibiotics. In addition, on overstepping the threshold to toxicity another excessive increase of the amino-glycoside antibiotics of the inner ear concentration could be noticed. The last procedure which in contrast to the normal accumulation may be designated as a toxic conditioned accumulation process, is likely to result from a disturbance of the membrane permeability.

In comparison other antibiotics like penicillin attain only the lowest level of the inner ear while tetracycline and polymyxin F (Colistin[®]) will not penetrate into the inner ear at all, thus lacking the ototoxic effect.

In this connection an attempt has been made to settle the point of question whether substances like pantothenic acid or oxothin which are supposed to diminish the toxicity of the streptomycetes antibiotics, take an influence on the concentration, particularly on the inner ear level of the amino-glycoside antibiotics. On the basis of these examinations, one is

inclined to believe that the protective action of oxothin has probably been created by the significant decrease in the antibiotic concentration both in the serum, the inner ear and other organs. The varying toxicity of the individual pantothenic and sulfate combinations of the oligomyces antibiotics may also be explained by their differing concentrations in the inner ear fluid. Hence, it seems not to be a question of an authentic detoxication, but merely a matter of a decrease in concentration, respectively of a reduced effect of the toxic antibiotics.

These findings make a correction of the previous concepts about the specific sensitivity of the inner ear indispensable. The designation "Specific" can only be given to the characteristic process of accumulation of the amino-glycoside antibiotics in the inner ear. The results obtained from a study of the intestinal mucosa of rats showed that here also, when the toxic substances administered in a correspondingly high concentration take effect, a similar picture of the injuries done to the superficial epithelial layer is created, as is known to exist in the kidney and the inner ear. Both the specific-ototoxic effect, as well as the detoxication tests of the amino-glycoside antibiotics, may essentially be defined as concentration effects.

F RÉSUMÉ

Des nombreuses théories sur le mode d'action toxique des antibiotiques du genre aminoglucoside, aucune ne peut expliquer pourquoi exclusivement l'oreille interne et le rein sont atteints, alors que tous les autres organes ne le sont pas. On se contentait d'accepter que les cellules de l'oreille interne possèdent envers ces substances une sensibilité spécifique. Cette hypothèse peu satisfaisante fut la raison de rechercher d'autres causes de cette activité spécifique.

Une recherche de la répartition et de l'écoulement en fonction du facteur concentration-temps des antibiotiques streptomyciniques toxiques dans le cobay donna les résultats suivants.

Tous les antibiotiques du groupe des aminoglucosides, aussi bien la streptomycine et la dihydrostreptomycine que la kanamycine et la néomycine s'accumulent dans les liquides de l'oreille interne et y sont retenus. Leur concentration dans l'oreille interne et dans les reins dépasse de plusieurs fois celle dans tous les autres organes et même celle dans le sang.

Plus ces substances sont toxiques, plus leur accumulation dans les liquides de l'oreille interne est élevée. Il y a apparemment une relation entre la concentration et l'ototoxicité des divers antibiotiques du genre aminoglucosides.

Les antibiotiques du groupe des aminoglucosides atteignent déjà à faibles doses atoxiques un niveau relativement élevé dans l'oreille interne. La cause en est vraisemblablement une élimination plus difficile et une rétention des substances pratiquement irrésorbables dans les espaces de l'oreille interne de ce groupe d'antibiotiques. Une accumulation comparable fut trouvée avec l'inuline, qui présente au point de vue de sa répartition dans l'organisme des propriétés pharmacologiques semblables à celles des antibiotiques streptomyciniques. En plus, avec le dépassement du seuil de toxicité survient encore une augmentation disproportionnée de la concentration des antibiotiques du genre aminoglucoside dans l'oreille interne. Ce dernier phénomène que l'on peut à l'encontre d'une accumulation normale, décrire comme étant un processus de cumulation dû à la toxicité est probablement à attribuer à un dérangement de la perméabilité des membranes.

D'autres antibiotiques, comme la pénicilline n'atteignent en comparaison qu'un niveau minimal dans l'oreille interne alors que la tétracycline et la polymyxine B (colistine[®]) ne sont absolument pas capables de pénétrer dans l'oreille interne et ne peuvent par conséquent non plus avoir d'activité ototoxique.

Dans ce contexte on chercha alors à résoudre la question de savoir si des substances comme l'acide pantothénique ou l'oxothine, qui prétendument doivent diminuer la toxicité des antibiotiques streptomyciniques, ont une influence sur l'écoulement en fonction du facteur concentration-temps des antibiotiques du genre aminoglycoside et particulièrement sur le niveau qu'ils atteignent dans l'oreille interne. D'après ces recherches, on doit admettre que l'effet de protection de l'oxothine est vraisemblablement basé sur la diminution significative de la concentration d'antibiotique aussi bien dans le sérum que dans l'oreille interne et d'autres organes. On peut probablement aussi attribuer la toxicité différente de chaque composé pantothénique et sulfurique des antibiotiques oligomycétiques à leur concentration différemment élevée dans les liquides labyrinthiques.

D'après cela, il ne s'agit pas d'une véritable désintoxication, mais purement et simplement d'une diminution de la concentration, respectivement de l'activité, des antibiotiques ototoxiques.

Ces résultats rendent nécessaire une correction des anciennes notions sur la sensibilité spécifique de l'oreille interne. On ne peut nommer spécifique que le processus caractéristique d'accumulation des antibiotiques du genre aminoglycoside dans l'oreille interne. On peut démontrer au niveau de la muqueuse intestinale du rat, que là aussi, lorsque les substances toxiques agissent dans une concentration relativement élevée, elles provoquent une forme de lésion de la couche épithéliale superficielle, histologiquement très analogue à celle que l'on connaît au niveau du rein et de l'oreille interne. L'activité spécifiquement ototoxique, aussi bien que les recherches de désintoxication des antibiotiques du genre aminoglycoside, peuvent être expliqués comme étant essentiellement des effets de concentration.

F RÉSUMÉ

Des nombreuses théories sur le mode d'action toxique des antibiotiques du genre aminoglycoside, aucune ne peut expliquer pourquoi exclusivement l'oreille interne et le rein sont atteints, alors que tous les autres organes ne le sont pas. On se contentait d'accepter que les cellules de l'oreille interne possèdent envers ces substances une sensibilité spécifique. Cette hypothèse peu satisfaisante fut la raison de rechercher d'autres causes de cette activité spécifique.

Une recherche de la répartition et de l'écoulement en fonction du facteur concentration-temps des antibiotiques streptomyciniques toxiques dans le cobey donna les résultats suivants,

Tous les antibiotiques du groupe des aminoglycosides, aussi bien la streptomycine et la dihydrostreptomycine que la kanamycine et la néomycine s'accumulent dans les liquides de l'oreille interne et y sont retenus. Leur concentration dans l'oreille interne et dans les reins surpasse de plusieurs fois celle dans tous les autres organes et même celle dans le sang.

Plus ces substances sont toxiques, plus leur accumulation dans les liquides de l'oreille interne est élevée. Il y a apparemment une relation entre la concentration et l'ototoxicité des divers antibiotiques du genre aminoglycosides.

Les antibiotiques du groupe des aminoglycosides atteignent déjà à faibles doses atoxiques un niveau relativement élevé dans l'oreille interne. La cause en est vraisemblablement une élimination plus difficile et une rétention des substances pratiquement irrésorbables dans les espaces de l'oreille interne de ce groupe d'antibiotiques. Une accumulation comparable fut trouvée avec l'insuline, qui présente au point de vue de sa répartition dans l'organisme des propriétés pharmacologiques semblables à celles des antibiotiques streptomyciniques. TRANSLATORS' PREFACE

De rosis audituque organo hist. ris anatomica by Julius Casserius (1581-1616) was published by Victorius Beldinus in Ferrara in 1601. The first consists of two treatises, the first dealing with the larynx and the second with the ear. The section on the larynx consists of 191 pages with 22 plates. Copper plates were used and were probably drawn and etched by the Swiss painter Joseph Murer or Maurer.

The translators of this work employed a microfilm facsimile obtained from the Armed Forces Medical Library (Acc. No. 10306). Since there appears to be no English translation of Casserius' book, an initial literal translation was made by J. H. Hamark. Then, M. Hadd read the literal translation editing the same for an scientific and conciseness, particularly of an anatomical nature. Finally the two translators combined their respective talents to obtain a more finished translation of this "Renascence medical work. Where required, the modern terminology for a structure is given, employing the nomenclature adopted by the I.A.N.C. and presented in their 1960 publication of the *Nomina Anatomica*.

The treatise on the larynx is composed of the author's expected serenissimo to his patron, epigrams, preface bibliography and index, followed by the body of three books. Casserius not only deals with structure and function of the larynx of human and domestic animals, but he also devotes a large portion of his work to describing theories of the voice. For Casserius, the larynx is the organ of voice and this is its purpose in the body. Because of the strong interest one of us (M. H.) has in the anatomy of the muscles and nerves of the larynx, we have confined our translation, for the present, to the first eight chapters of Book I.

Like his contemporaries and teachers, Casserius was greatly influenced by Galen. Which ideas or observations are original to Casserius or must be attributed to Galen is debatable. Certain by Casserius discussion of the mechanism of the recurrent nerves is Galenic (*De Uss Partium*). But the detailed description Casserius gives of the laryngeal muscles has no equal in the contemporary anatomy of his day. If he stood upon the shoulders of great men to see further as we all do, and did not acknowledge their support, we should chastise him, but he is rarely guilty of this fault. It is true that his work does suffer from the inherited scholasticism of the Middle Ages. William Harvey's famous publication was twenty-seven years in the future and scientific thinking was still teleological. But Casserius, a brilliant man, future students of anatomy could approach his work without the preconceived notions we all obtain from studying the standard textbooks of anatomy (with their beautiful illustrations) guiding our knife on its proper course. He learnt his discipline by that valuable but laborious method of making his sections by himself. Therefore if the reader does not always find Casserius' description of the course of muscles as he would expect or was taught, let him return to the dissecting room with an unprejudiced mind and without notes or textbooks.

TRANSLATORS' PREFACE

De vocalis et linguae organi historia anatomica by Julius Casserius (1561-1616) was published by Victorius Baldinus in Ferrara in 1601. The folio consists of two treatises, the first dealing with the larynx and the second with the ear. The section on the larynx consists of 191 pages with 22 plates. Copper plates were used and were probably drawn and etched by the Swiss painter Joseph Murer or Maurer.

The translators of this work employed microfilm of calcule obtained from the Armed Forces Medical Library (Acc. No. 10306). Since there appears to be no English translation of Casserius' book, and his literal translation was made by E. H. Rismark, then, M. Hadd read the "literal translation" editing the same for any self-evident inaccuracies, particularly of an anatomical nature. Finally the two translators combined their respective talents to obtain a more finished translation of this Renaissance medical work. Where required, the modern terminology for structure is given, employing the nomenclature adopted by the I.A.N.C. and presented in their 1908 publication of the *Nomina Anatomica*.

The treatise on the larynx is composed of the author's expected serialisms to his patron, epigrams, preface, bibliography, and index, followed by the body of three books. Casserius not only deals with structure and function of the larynx of human and domestic animals, but he also devotes a large portion of his work to describing theories of the voice. For Casserius, the larynx is the organ of voice, and this is its purpose in the body. Because of a strong interest on our part (M. Hadd) has in the anatomy of the muscles and nerves of the larynx, we have finished our translation, for the present, at the first eight chapters of Book I.

Like his contemporaries and teachers, Casserius was greatly influenced by Galen. Which idea or observation are original to Casserius or must be attributed to Galen is debatable. Certainly Casserius' discussion of the "mechanism of the recurrent nerves" (Galen) (*De larynx Partium*). But the detailed description of Casserius of the laryngeal muscles has no equal in the contemporary anatomy of his day. If he stood upon the shoulders of great men to see further as we do, and did not acknowledge their support, we should hate him, but he is rarely guilty of this fault. It is true that his work does suffer from the inherited scholasticism of the Middle Ages. William Harvey's famous publication was twenty-seven years in the future and scientific thinking was still teleological. But Casserius, like any future student of anatomy could approach his work without the preconceived notions we obtain from studying the standard textbook of anatomy (with their beautiful illustrations) guiding our knife on its proper course. He learned his discipline by that invaluable but laborious method of making dissection by himself. Therefore if the reader does not always find Casserius' description of the course of muscle as he would expect or was taught, let him return to the dissecting room with an unprejudiced mind and without notes or textbooks.

AN ANATOMICAL HISTORY
ON THE ORGANS
OF VOICE AND HEARING

Harmoniously Arranged, With Outstanding and Faithful
Precision and Care Discussed in Two
Treatises Illustrated by
Various Copper Printed
Diagrams

by

JULIUS CASSERIUS OF PIACENZA

Philosopher and Physician at Padua

Practitioner of Theoretical and Applied Medicine

The Three Books of the First Treatise on the
Anatomical History of the Larynx,
the Organ of Voice,
by Julius Casserius of Piacenza,
Philosopher, Physician and Anatomist

BOOK ONE ON THE STRUCTURE OF THE LARYNX,
THE ORGAN OF VOICE

CHAPTER I

The Excellences of the Voice and its Worthiness
methodology for treatment of topics

Because I have reviewed the usefulness of the subject which I am going to discuss and have weighed its merits with careful deliberation, now as I set out to consider with utmost precision the instruments of voice and hearing (the larynx and the ear respectively) I sense a certain prompting to investigate a more important subject matter. For it seemed a worth-while thing to make some prefatory remarks and bring into focus the magnificence as well as the purpose of each organ. The excellence of these organs merits much praise and honor since without them we could have neither voice nor hearing. No slipshodness, then, is to be attributed to my intention to begin with that exquisite handiwork of nature the organ of voice which Galen calls the larynx. I shall attempt to outline to some degree of completeness the excellence, utility and necessity of voice. Thus each individual will have a thorough appreciation of the importance of a studied and accurate treatise on the larynx, of the value to be placed on such a work, and the need for it. For when the larynx is formed as nature intended, voice too is produced in a natural way but if the larynx is not shaped naturally voice is uttered in corrupted fashion and if the larynx is totally lacking, so is voice. I shall speak not in a full oratorical style (for in proportion to the unpeakable richness of the material that appears in the celebration of voice its majestic dignity will shine forth, even like the sun, without the harmoniously modulated sound of the word)—I shall speak, then, in a philosophical manner with bare and simple words. And such, as Euripides says, are the words proper of the truth. I shall, furthermore treat all the virtually countless topics which appear on this rich field of discourse. For if I decided to speak in proportion to the abundance and fullness of the mate-

ria! I would run out of paper and ink, by the gods, sooner than I would run out of something to say. Suppose you were to review what the above mentioned individuals have, with the greatest wisdom handed down from ancient times about voice—suppose you were to consider everything which we daily experience during our mortal lives—suppose, finally you were to examine what has been sanctified on voice in our monuments of sacred literature—do this, and immediately the subject matter like an overflowing river will rush down on you resulting in the need for you to admit that you would be overwhelmed much more by the abundance of things to discuss than by the lack thereof. Onward, then to trace our beginning from the writings left by the ancient philosophers! Is it not the case that Aristotle who is easily the foremost of all philosophers, seems to place before our eyes in a marvelous fashion the excellence, utility and necessity of voice? that along with Galen the keenest of investigators into nature's secrets, he announced that speech is the interpreter of our reasoning and intellect, the unfold of all our conceptual thoughts and, in like manner the active component of our soul? For our verbal expressions are the indices to the passions of our inner being (Periher first said that). It was perhaps with this understanding that Speusippus, a very important writer claimed in *Platonius definitionibus* that speech is an oral product in accord with our reasoning, and therefore it is judged to be no mean index to our emotions. On this account the Physiologists have agreed on the following equivalences: if his voice is without force, it shows that the man is weak and timid; if it is coarse, that he is deceitful and haughty; if it is clear that he is clever and talented; if it is heavy that he is brave and persevering; if it is tremulous, that he is envious and lazy; if it is deep that he is rash and harmful; if it is rough harsh and changing, that he is a vain and flippant man who loves luxury; and if it is gentle, that he is calm and withdrawn. And so in the divine words of Plato just as the birds are distinguished by their song and jays by their sound so the talents and natural bent of men are recognized as distinct by their discourse. Thus, when with many pleas, a certain man prevailed on Socrates to give a judgement about the character of a slave who had been brought before him, he said to him: Speak, and I shall know you! By this comment he clearly indicated that a youth of distinguished prospects is most easily known from the way he talks. It was indeed a comment worthy of so great a philosopher. So Diogenes used to say that he always wondered why we rested content with a look only when buying a man but would buy a jar or some piece of handiwork only after touching it or listening to its sound. Plutarch recounts an episode not dissimilar from this one in his *Symposiacs*, concerning the preeminent Simonides while the guests, eating and drinking were enjoying themselves at the table with jokes, witticisms and pleasantries, he would observe some individual who was lost in silent thought and saying nothing, and then assert that if this individual really was a wise man his silence was foolish, but that if he was a foolish man then it was wise. Since, therefore our voices are indices of our inner

leanings, there is the greatest necessity to compare our thoughts about those matters and our knowledge. For on the one hand our intellect, endowed with such nobleness that it is not associated with any organs, is by its nature single, immaterial and immortal and does not at all stand in need of the aid and help of the senses in order to exercise its function of understanding. On the other hand, however, it is closely connected to our mortal, solid and earthly body and, as the poet sings, earthly actions I hunt it—it is in fact so blunted by our moribund flesh that without the aid of the senses it could not attain to thought or knowledge. Consequently Plato was right in naming the senses the intermediaries and, as it were, the servants of the mind, and saying that they were the guides that lead to the truth. Please remember too, the claim of his student Aristotle: "nothing is understood except what has first been perceived by the senses, since they pave the way, so to speak, for understanding the matter in question." Therefore he established, in another work, that if any man should by nature be denied one of the senses from birth, he would necessarily lack some knowledge.

Among all the senses two are especially suited for gaining knowledge: the eyes and the ears—the eyes have been established by nature herself to inculcate objects close at hand; the ears, to hear of these objects when they are reported by somebody else. But nature again, willed speech to be the instrument responsible for sharing and communicating the ideas of the mind. If someone, therefore, should suddenly do away with speech, he, it seems, will have removed the instrument necessary for garnering knowledge. Indeed, will have taken from the universe its sun, the very chief and guide of the stars. And not only innate and scientific skills need the aid of speech, but the arts of free man and slave cannot be taught, in fact, cannot even exist or be practised without speech. Should you set wood before the carpenter and iron before the smith without telling them that they must fashion a bench or a key respectively from their materials, all their labor will have been undertaken in vain, for they will make no object from their materials. Nor should one judge that it would be any different in the case of government and magistracies. For what is it that promulgates the laws necessary for the preservation of peace among men? Speech. What declares statutes? Speech. What defends the innocent man in the law-court, acquits him of his accusation of wrong? What charges the guilty man, proves the accusation lodged against him, condemns him, punishes him? Speech. Speech, I say, the preserver of peace and justice. Speech is so loyal a companion and helpmeet of justice that it does not adjudge defendants without an open hearing of their case. It raises up the oppressed and lifts high those who lie low. It means destruction for the wicked, protection for the innocent, terror for the base and delight for the upright. On this account the books claim, Alexander the Great was praised, since he refused to let that most abominable of men, Philotas, be dragged off to his punishment before his defense had made its plea—and that though Philotas, along with his father Iphimenes and some other men, was forming a conspiracy to murder Alex-

rial I would run out of paper and ink, by the gods, sooner than I would run out of something to say. Suppose you were to review what the above mentioned individuals have, with the greatest wisdom handed down from ancient times about voice: suppose you were to consider everything which we daily experience during our mortal lives: suppose finally you were to examine what has been sanctified on voice in our monuments of sacred literature—do this, and immediately the subject matter like an overflowing river will rush down on you resulting in the need for you to admit that you would be overwhelmed much more by the abundance of things to discuss than by the lack thereof. Onward then to trace our beginning from the writings left by the ancient philosophers! Is it not the case that Aristotle who is easily the foremost of all philosophers seems to place before our eyes in a marvelous fashion the excellence, utility and necessity of voice? that along with Galen the keenest of investigators into nature's secrets, he announced that speech is the interpreter of our reasoning and intellect the unfold of all our conceptual thoughts and, in like manner the active component of our soul? For our verbal expressions are the indices to the passions of our inner being (Perihier first said that). It was perhaps with this understanding that Speusippus, a very important writer claimed in *Platonius definitionibus* that speech is an oral product in accord with our reasoning, and therefore it is judged to be no mean index to our emotions. On this account the Physiologists have agreed on the following equivalences: if his voice is without force it shows that the man is weak and timid: if it is coarse that he is deceitful and haughty: if it is clear that he is clever and talented: if it is heavy that he is brave and persevering: if it is tremulous, that he is envious and lazy: if it is deep that he is rash and harmful: if it is rough, harsh and changing that he is a vain and flippant man who loves luxury: and if it is gentle that he is calm and withdrawn. And so in the divine words of Plato, just as the birds are distinguished by their song and jars by their sound so the talents and natural bent of men are recognized as distinct by their discourse. Thus, when with many pleas, a certain man prevailed on Socrates to give a judgement about the character of a slave who had been brought before him he said to him: 'Speak and I shall know you'. By this comment he clearly indicated that a youth of distinguished prospects is most easily known from the way he talks. It was indeed a comment worthy of so great a philosopher. So Diogenes used to say that he always wondered why we rested content with a look only when buying a man but would buy a jar or some piece of handiwork only after touching it or listening to its sound. Plutarch recounts an episode not dissimilar from this one in his *Symposiaca*, concerning the preeminent Simonides: while the guests, eating and drinking were enjoying themselves at the table with jokes, witticisms and pleasantries, he would observe some individual who was lost in silent thought and saying nothing and then assert that if this individual really was a wise man his silence was foolish, but that if he was a foolish man then it was wise. Since therefore our voices are indices of our inner

speech) inflames men to virtue and to notorious deeds of evil. It teaches the wretched how to seek for help. It has restored spirit to the timid, control to the impetuous, skill to the idle, calm to the angered, solace to the unhappy, hope to the despairing—in short, it has virtually restored life. But if we may now turn our argument from the perceptible world to the world of the spirit and hold in abeyance the words of naturalists, we have the opportunity of asserting the opinions of Theologians about speech and words. I shall say that so great is the nobility of speech and words that the son himself of God wanted a term named, and that in a single sound, IEHI, IEHI that is to say, "Let there be, let there be." In amazing fashion he created the amazing and marvelous machine that is the entire world, as well as the almost countless species of things in it. Indeed, after the fall of our first parent Adam, when this voice had been uttered—Where, oh where are you, Adam?"—he instilled a great fear in him, as the Scripture testifies from the third chapter of Genesis. There we read, "I have heard your voice, oh Lord, and I was afraid." Further, in chapter 17 of Matthew in the New Testament, when the boat of the disciples was being tossed about by enormous waves because of contrary winds and a severe storm at sea, and our Savior walked on the waters, the spirit of the disciples, being in dire straits and filled with fear, was raised and strengthened by speech. For as soon as Christ spoke this speech for their ears—"Have faith, I am He, do not fear"—suddenly the trembling was driven in rout from their hearts and they all recovered. Likewise (again in Matthew 17) the trembling disciples were comforted when Christ uttered these words, "Up, let us go from here (and) do not be afraid." What more? The sacred scriptures proclaim that thanks to speech, voice was restored by Christ and the Apostles to the mute, hearing to the deaf, light to the blind, health to the sick, life to the dead, and countless other miracles were performed. In sum, the voice of the Lord is in virtue and the voice of the Lord is in magnificence.

To this day from the time of the Apostles and their successors, speech has made the shining light of the Christian religion flash forth—not only in our own lands, but in the remotest region of this great world. The brilliance of the Faith has increased, the darkness of wrongs has been routed, the disgrace of the cross has been done away with, the sacred and holy Evangel of Christ has been preached, heresies have been destroyed and heretics completely laid low. By means of speech the thanks due to God are rendered to Him and sacred prayers are offered up. In our action we ask for the only help and in our difficulties we implore consolation and alleviation from God. By speech will this universe one day be destroyed when the heaven will ignite in heat when the son of God appears in the clouds, the

The next two records are extremely useful in the microfilm. Despite our best effort we can make no satisfactory sense of the Latin which is here subject of a *Patre*.

This is good example of the semantic problem caused by Cassius. In our text both speech and voice; in the Latin, both word (*Verbum* and *sonus*) are the same.

ander! On the supreme excellence of speech its marvelous usefulness! Speech renders service to writers of music comedy and tragedy as well as to orators. By its aid is commerce carried on. It enters into contracts and breaks them and it strengthens both those free of debt and those whose fortunes have been shattered. Speech calls men away from the way of the beasts and from their enormous savagery towards gentleness and an upright relationship in their dealings. If men ever swerve from the straight path of life speech leads them back onto the road of safety. Speech points out men's spiritual suffering and confusion but it also sets them in motion and allays them. Speech builds states, comforts the wretched, causes marriages to come about carries on the business affairs of men and is judged to appoint an eternal peace among them. We do not recognize however speech as useful and necessary only in peace but also in war. Speech proclaims the state of war to the enemy instructs us to fight to the finish when engagements have started gives courage to the terrified and puts hostile squadrons to flight. Oh Speech you gather soldiers together call back those who flee ease the burden of the overwhelmed stir your men to battle and strike panic terror in the hearts of the enemy. And in this way alone it was the custom not only among the barbarians but also among the Romans to utter a shout before the attack and during the actual fighting to terrify the enemy and encourage one's own side—and this is vouched for in the historical writings of Livy Tacitus and Caesar. Therefore when Paulus Aemilius was teaching young men to fight intrepidly he used to say that the enemy were frightened and put to flight more by words and speech than by the sword and the hand. Indeed Livy the distinguished historian wrote that the successful or unsuccessful outcome of war was indicated on the evidence of speech. Shouting he says, was the first index as to how the situation was likely to eventuate—be it somewhat excited quite frequently answered by the enemy different from that of the Romans, unequal, lazy or repeated often. Finally nature, the parent of all things, recognized that so great was the usefulness of speech that she endowed living creatures with it or at least a sound very similar to it. Thus they could guard against harm seek their living pursue pleasure and avoid difficulties. Men especially could be moved and stirred by sweet wheedling speech to propagate the species. How aptly and admirably does that plaintive voice of the owl unfold its inner feelings, passions and loves, and point up its anger. The same is the case for the mournful sound of the kite the groaning plaints of the turtle-dove the repeated sound of the cuckoo, the sweet chattering of the nightingale and the chirping of sparrows. To such an extent do they seem in uttering their sounds, now to lament now to rejoice and again now to be looking for one thing now to be asking for something else. Nothing at all, moreover, leave us no room for doubt on this matter about whom the poets tell here and there that they keep weeping, for wrong, suffered long ago. Martial in particular so relates Philomela the nightingale beweeeps her impious crime.

Speech finally (and let me here in one speech sum up all my praises of

speech) inflames men to virtue and to notorious deeds of evil. It teaches the wretched how to seek for help. It has restored spirit to the timid, control to the impetuous, skill to the idle, calm to the angered, solace to the unhappy, hope to the despairing.—In short, it has virtually restored life. But if we may now turn our argument from the perceptible world to the world of the spirit and hold in abeyance the words of naturalists, we have the opportunity of asserting the opinions of Theologians about speech and words. I shall say that so great is the nobility of speech and words that the son himself of God "wanted a term named, and that in a single sound IEHI, IEHI that is to say, 'Let there be, let there be'" in amazing fashion he created the amazing and marvelous machine that is the entire world, as well as the almost countless species of things in it. Indeed, after the fall of our first parent Adam, when this voice had been uttered—Where, oh where are you Adam?"—he instilled a great fear in him, as the Scripture testifies from the third chapter of Genesis. CHAPTER II

On the various designations of the term Larynx and on synonyms for the indicated part

In my proposal to examine the anatomy of the Larynx, the true and genuine instrument of voice I shall pursue the subject matter uninterrupted and without any ambiguity. That I however may be able in the course of my treatise to move about more conveniently and that the reader may more easily understand what will be set forth about this organ in my fine yet difficult explanations, I shall first consider in review the various designations of Larynx as well as whatever other names the organ of voice has been allotted. Thereupon girding myself for the definition of my actual subject I shall very clearly summarize its essence and all my diligent research which can bring to bear on understanding it. To facilitate learning and understanding this summary—as, I suspect will presently be clear—will not come in the position in which a good number of anatomists usually put it in setting forth their history of the parts of the body, namely when they switch the discussion from the parts of the body to its total structure. For I proceed by the opposite and as it were free method from the whole to the parts. The Nostrates [sic]¹ then along with the Greeks recognize the head of the harsh wind pipe [trachea] by the name larynx or larynga. Aristotle on the contrary for some inexplicable reason understood the head of the wind pipe by this name. Calen in the seventh book chapters one and three of *De usu partium* at one point (and here he incorrectly appropriates this term) gives the name larynx to that little part which lies between the pharynx and the harsh wind pipe² at another point (and here he is more correct and accurate) he means by larynx that part which is separated and distinct from the pharynx proper and the other indicated parts. On this matter see Calen in his book *De musculorum dissectione* chapter 16 as well as Book I chapter 3 of *De motu musculorum*. There are some who identify the head of the wind pipe and the organ of breathing and the knot of the throat [prominentia laryngis] with the larynx. Even if you should read many authors, these are the meanings given to the term larynx among them. We however believe with Calen that the head of the trachea is designated by this term. Now just as we find varied meanings for the term larynx so there are varied

¹ Caesari w. probabl. referri g. t. th. f. l. w. r. a. f. h. r. a. l. t. r. a. t. f. C. e. o. s. the f. m. v. l. v. n. d. r. i. nat. m. l. t.

² On the basis of the edited passage I. G. I. (VII. 1, III) we find it understood Caesari dissection th. t. G. I. I. m. l. l. g. th. term.

names assigned to that part which we are calling larynx. For example, in the Canon of Avicenna and Averroes it is called the head of the lung, which, in the latin idiom *Augena* attributes to the Arabic. I pass by in silence the invention of Hall Abbas as utterly incompetent and strange—he calls it the collarbone. This term, collar-bone should, I think, be rejected as excessively vague common to several parts yet also more suitable to others, and in correctly appropriated by Hall Abbas. Nor do I add the name *epiglottis* to the list of other names for this part, although that would agree with the ideas of certain people. My reason is that the etymology of the term shows it to be clearly misleading and inappropriate. It is made up of the prepositional prefix *epl* (meaning *upon* or *above*) and the noun *glossa* (meaning *tongue*) which is spelled *glotta* in the Attic dialect. Hence the term *epiglottis* can designate nothing except some kind of tongue-like covering, as will become more clear in what follows. That term however which the admittedly great scholar Hesychius used I gladly add to my list of other terms. He named the part in question the *esophagus*.

CHAPTER II

On the various designations of the term Larynx and on synonyms for the indicated part

In my proposal to examine the anatomy of the Larynx the true and genuine instrument of voice I shall pursue the subject matter uninterrupted and without any ambiguity. That I however may be able in the course of my treatise to move about more conveniently and that the reader may more easily understand what will be set forth about this organ in my fine yet difficult explanations, I shall first consider in review the various designations of Larynx, as well as whatever other names the organ of voice has been allotted. Thereupon girding myself for the definition of my actual subject I shall very clearly summarize its essence and all my diligent research which can bring to bear on understanding it. To facilitate learning and understanding this summary—*as, I suspect will presently be clear*—will not come in the position in which a good number of anatomists usually put it in setting forth their history of the parts of the body namely when they switch the discussion from the parts of the body to its total structure. For I proceed by the opposite and, as it were free method from the whole to the parts. The Nostrates [*sic*]¹ then along with the Greeks recognize the head of the harsh wind pipe [trachea] by the name larynx or larynga. Aristotle on the contrary for some inexplicable reason understood the head of the wind pipe by this name. Galen in the seventh book chapters one and three of *De usu partium* at one point (and here he incorrectly appropriates this term) gives the name larynx to that little part which lies between the pharynx and the harsh wind pipe² at another point (and here he is more correct and accurate) he means by larynx that part which is separated and distinct from the pharynx proper and the other indicated parts. On this matter see Galen in his book *De musculorum dissectione* chapter 1; as well as Book I chapter 3 of *De motu musculorum*. There are some who identify the head of the wind pipe and the organ of breathing and the knot of the throat [prominentia laryngea] with the larynx. Even if you should read many authors, these are the meanings given to the term larynx among them. We however believe with Galen that the head of the trachea is designated by this term. Now just as we find varied in naming forth the larynx so there are varied

worthy of praise than its usefulness. For to this part especially is entrusted the action of the larynx, and voice is formed by it—which is the specific function of this organ. In marvelous fashion air passes through and, being compressed, is thrust forth so as to produce voice. Hence not without good reason, its inner surface is carefully fashioned, and lightly smeared with some sort of mucosa [tunica mucosa]. There is little moisture on it. Indeed it is wetter than necessary to the extent that it impedes the formation of voice. Because of this there is that well known hoarseness which the catarrh be-
 gets on.

This brings us to its position. The part which sticks out and is hump-shaped lies in the anterior position. It is, as it were, pug-nosed and pressed down, and laying claim also to a posterior position for itself touches the esophagus. The upper or higher portion where it lies beneath the epiglottis, looks towards the gullet and little column. The lowest part is located above the trachea, as though it were its head, and is like the musical instrument which flute players use. In that way trumpets (commonly called trombones) curved and straight horns, in short all wind instruments like pipes and others of that sort, have a head. Just as we produce the most perfect sound relaying on this skillfully crafted instrument, so nature emits, by means of that head, voice which is highly sonorous and thoroughly pleasing to the ears. From this description of its location, the complex of the larynx is, I suspect, sufficiently clear and obvious. Its connection to the cartilages, with the harsh wind-pipe with the binding of both the special and the common muscles, with the esophagus, with the thorax, with the hyoid and with the higher parts with the brain, the help of the nerves, with the heart and aid of the arteries. These comments shall suffice for the establishing of those parts because of which we have called the larynx the first and proper organ of modulating voice as well as for the brief description of its components. The body of the larynx, then, is joined together from a simple union of its parts, not from any change in them. As a result the larynx has no other constitution than its parts, nor any other consequences or differing accidents.²

I intend to leave for the proper place a more extensive treatment of these matters, so now I gird myself for an explanation of the parts, first which make up the larynx and, second with by which it has been provided for the modulation of voice. And although the natural order prescribes that the former should be discussed before the latter still the arrangement of the plates demands that we abandon and change this order and treat first of the muscles, then of the nerves.

² I use consequences (consequentia) and accidents (accidentia). Casserius refers to philosophical notions of primary and secondary purposes.

CHAPTER III

On the Definition of the Larynx

After I have reviewed the various names of that part with which my dissertation is concerned and since the ambiguity of the part most closely corresponding to it has been removed I offer the following definition of the Larynx. It is the organ which consists of the cartilages [cartilaginea laryngis] extending the glottis [rima glottidis] and of its membranes—an organ endowed with muscles and nerves, first and foremost constructed to produce voice. I said "first and foremost" having speech in mind on the authority of Galen for these are his very words in Book 7 chapter 10 of his *De usu partium* where he distinguishes the larynx from the thorax. For although the thorax [pulmo] provides the material of voice it will justifiably be considered as the secondary instrument of it. Here and there in several places, he also called it an organ. For since that which causes some action is an organ in Galen's opinion this term in particular is appropriate yet if it causes the formation of voice, no one will deny that it is an action. However since every organ is a body yet certain parts of bodies are soft or hard some rare or dense, others thick or slight I claim that the body of the larynx is hard, dense and thick. I do this on the grounds that cartilaginous bodies are worked into its make-up. In like manner the larynx is large and ample consisting of the three dimensions of length, width and depth there is also a certain protuberance [prominentia laryngea] on it which in men is very conspicuous, but rarely so in women. The reason for the variety of the larynx is, according to the opinion of certain individuals, due to the composition of this protuberance—because certain gland like [glandula laryngea] bodies which are almost coterminal with the larynx, in filling up any hollow or empty spaces, make the chamber equal in women. The shape of the larynx is round and circular with however a certain slanting quality to it. In its anterior portion it is absolutely circular but in the posterior part from which it faces the esophagus, it gradually changes from a perfectly circular shape and attains some length. Therefore this part because of its structural outline, is likened to a vessel called the *arytaene*¹ [cartilago arytenoidea] but with a spout with which we pour water for those who would wash their hands. Moreover a shape of this sort is not without its advantages, since it is crisscrossed with passages and apertures. For there is within the body of the larynx an aperture which is called the little cleft [rima glottidis] fissure or rent of the larynx or glottis. Its grace is no less

¹ A Greek word which means "pitcher"

for the present I have set myself the task of examining only the muscles of the larynx. The remaining two [musculi thyrohyoidei], which verge considerably to the side emerge from almost the entire lower border of the hyoid. This is the case in man, but in other living things (especially quadrupeds) the situation is different for in the middle of their passage, the muscles are united, at the bottom, they are divided and split in two. Therefore we can rightly call them two-horned or two-footed because they consist of two legs. Of these one part is fixed in the shield shape [cartilago thyroidea], the other in the hyoid bone—and that most conspicuously. In origin they are fleshy broad, very close to the internal sides, and continuous. And this is how they lie advancing gradually from their place of origin with straight-down fibers, they settle finally in the same lower part of the first cartilage opposite which are the muscles which precede these and are firmly fixed and exactly the same insertion is preserved. Galen, Vesalius, Fuchsius and Realdus add other muscles to the four already mentioned. But whether they should be considered one, as did Columbus, or even two, as did Galen Vesalius and Fuchsius, observation itself makes unclear. Forced by the certainty of what I see however I agree with Realdus in this matter namely that it is only one. But I differ from him as well as from the rest, in that I believe that although it bur is forth from the shield shape it should in no way be considered among the common laryngeal muscles. For if nature had shaped this muscle only for the sake of the larynx, undoubtedly it would encircle the esophagus only very little otherwise this muscle would greatly hinder rather than aid in the swallowing of food or drink. Provident nature would have been bound to enclose the gullet not with this muscle but to extend the gullet from one extremity of the shield-shape to the other keeping the esophagus intact. Let us, therefore prompted by dissection alone say that this muscle serves the larynx neither especially nor by itself but only incidentally—as its structure and position makes amply clear. For it originates on both sides of the thyroid, along its entire length which is made up of crosswise fibers in a half circle. It then advances to a point where it girds the esophagus in a circle whereby it serves the swallowing of food and drink by a sort of involuntary movement, and also aids the natural faculties in passing down food and drink. Moreover while these muscles have movement for the sake of the gullet, the first laryngeal cartilage [cartilago thyroidea], to which it is attached, is necessarily constricted and tightened. Hence it aids the larynx—not in a primary or inherent way but by chance and secondarily. Therefore, at the suggestion of my observation I conclude that this extra muscle not only *can* not be reckoned as one of the common laryngeal muscles, but in fact belongs to them only by accident. So Galen says, in Chapter 7 of his book on dissection of the instrument of voice. “The shield shaped cartilage in the upper area is bound

Although apparently not differentiated by Casserius separate muscle, he appears to be describing the course of *musculus constrictor pharyngis inferior pars thyropharyngea* and *pars retropharyngea*.

CHAPTER IV

On the common muscles of the larynx not including an enumeration of all its muscles

The muscles of the larynx are of two kinds the common [*musculi laryngis externi*] and the special [*musculi laryngis interni*]. "Common" is the name given according to all scholars versed in dissection to those muscles which have their origin outside the larynx but end in it. "Special" is the name given to those muscles which originate from the larynx and in turn have their insertion circumscribed in it. I imagine it is accurate enough to think that this nomenclature derives from practical experience and not from any artificial criteria. There is, however, no agreement among the authorities on the number of all the muscles which serve this organ. Calen along with Fuchs and Vesalius (in *De usu partium* VII xi xii and XVII iv) asserts unequivocally that the larynx, as a self-contained structure is moved by twelve muscles but as a structure also of other parts, he claims it is moved by only eight muscles. In all then he counts twenty muscles for the larynx. Vicenna, on the other hand thinks there are eighteen muscles and there are even some who have not hesitated to enumerate thirty two muscles. It is certainly not my intention to contradict either Calen or any other skilled investigators (perhaps they busied themselves more frequently with the dissection of other animals than of man) but I shall maintain fearlessly what I have been allowed to observe in the human larynx—not once but again and again. There are then exactly thirteen muscles, of which four are common and the rest special and thus do I reject the opinion of Columbus, who made a claim for fourteen muscles.

Taking my beginning from the common muscles, I claim to have observed that the first two of these [*musculi sternothyroidei*] break out from the superior and inner part of the sternum where it juts out in the neck where the first two muscles of the hyoid bone come forth. Initially these muscles are membranous, but widening and then they advance upwards over the anterior region of the larynx wind pipe becoming fleshy and a little broader. They continue until fleshy & they enter the lowest part of the first thyroid cartilage. On their body one can not certain nodes or nerve-like markings called circumscriptions. In the cracks. The same thing is visible on the straight abdominal muscles (which I shall consider in the proper place since

The Latin phrase is *prima cartilago thyroideae* and therefore with it I take the first thyroid cartilage but structurally we fall to find out what Calen means by *prima* "first"

CHAPTER V

On the Special Muscles of the Larynx, generally considered, and on the first pair in particular

I believe I have satisfactorily explained those muscles of the larynx called common. Now that I intend to treat the muscles proper of the larynx, I shall describe their number, location and true differences. Authorities vary greatly on the matter of their number: some like Galen, Fuchsius and Vesalius think there are twelve, others, fewer. But I have had the opportunity to observe without prejudice in all animals, (for example cows, horses, pigs, sheep, men) nine muscles in all, as a result of careful dissection of most of these muscles. My drawings make this clear. Even though that small muscle ascribed to the arytenoid possesses two bellies (*musculus arytenoideus transversus*, *musculus arytenoideus obliquus*), however unclear by means of which a distinction seems to make a fifth pair and the muscles are commonly thought to number ten, nevertheless its structure and use clearly testifies to the fact that it is a single muscle. Careful inspection will reveal that this is the truth as far as its structure is concerned. Concerning its use I shall have a thing or two to say in passing. Every muscle performs its specific task through contraction. Therefore if this muscle is a double one set against itself it will necessarily produce a double and opposite action as long as it moves by contraction, which corresponds to its principle. Clearly then, when a muscle acts not by a double and contrary movement, but only by a simple movement, there will be only one not two muscles—unless of course one should believe that the muscle operates contrary to the edicts of nature. But I would not deny that the muscle is tendinous in the middle. This I believe serves the purpose of strengthening it and making it solid so as to prevent its suffering the inconvenience of rupture—a matter worthy of some concern—during its constant movement and agitation with the arytenoid. Hence I am justified in excluding the tenth muscle from the others. Furthermore of these nine those which make up the first pair are two (*musculi cricothyroides*), not four as Vesalius believed (in Chapter 20 of Book II of his great work) and also Sylvius, Fuchsius and several other anatomists. They claim that these muscles regulate the movement of the shieldshape along with the cricoid. And Vesalius, an otherwise skilled and especially careful anatomist, places two pair of muscles along either side of the shieldshape—one pair consist of those which verge to the front (*pars recta*) and lie on top of each other the other pair (*pars obliqua*), of those which, like the intercostal muscles, intersect each other crosswise with fibers. Vesalius believed that the first of these muscles, the exterior ones, had

together by those muscles which encircle the gullet growing out from its [cartilago] uppermost parts. It must be established with certainty that I know that its movement is accidental, not inherent. I cannot in truth posit two muscles, as the authors above mentioned do on the basis of my dissections. For since it springs forth from the posterior part of the mouth that lies opposite the vertebrae of the neck and runs the smooth and membranous length of the gullet without interruption it is obvious that one can in no way speak of two muscles. Arising from its own full and fleshy origin towards the front, it is fixed in the sides of the thyroid cartilage along their length. As a result of my personal observation it is obvious that no division or membranous line runs along those filaments which could persuade me that one should consider this muscle doubled. Therefore it seems that those have good reason to depart from Calen's view who said this muscle was one because it enfolds the esophagus in a circle-like sphincter. Calen supposed it was a double muscle one on each side and these are his words in Chapter 2 of his book on dissection of muscles. Two other muscles arising one on each side in the posterior extremities of the shield shape are fixed in the gullet and they likewise embrace the gullet like sphinctoral constrictors. These bind the cartilage together tightly.

Therefore no more than four common laryngeal muscles should be recognized. For in my opinion we cannot and should not count the other one among the common laryngeal muscles, as does Vesalius—not even if he shows distinctly that many other muscles arise from the inner part of the hyoid and that individual muscles on either side are fixed in the base of that cartilage which is called the epiglottis. For their function is to raise the epiglottis, the lid of the larynx when it is shut in the swallowing of food or drink to prevent breathing from being restricted. Consider this view to be most in harmony with the truth as far as certain animals are concerned in cows, pigs and all quadrupeds. It is abundantly clear. But in the case of man on applying complete diligence in dissection in no way will it be possible to find such a muscle in the root of the epiglottis, a subject which will be discussed in the proper place.

CHAPTER V

On the Special Muscles of the Larynx, generally considered and on the first pair in particular

I believe I have satisfactorily explained those muscles of the larynx called common. Now that I intend to treat the muscles proper of the larynx, I shall describe their number location and true differences. Authorities vary greatly on the matter of their number some like Galen, Fuchsius and Vesallus think there are twel — others, fewer. But I have had the opportunity to observe, without prejudice in all animals, (for example cows, horses, pigs, sheep, men) nine muscles in all, as a result of careful dissection of most of these muscles. My drawings make this clear. Even though that small muscle ascribed to the arytenoid possesses two bellies [musculus arytenoideus transversus, musculus arytenoideus obliquus], however unclear by means of which a distinction seems to make a fifth pair and the muscles are commonly thought to number ten, nevertheless its structure and use clearly testifies to the fact that it is a single muscle. Careful inspection will reveal that this is the truth as far as its structure is concerned. Concerning its use I shall have a thing or two to say in passing. Every muscle performs its specific task through contraction. Therefore if this muscle is a double one set against itself it will necessarily produce a double and opposite action as long as it moves by contraction, which corresponds to its principle. Clearly then, when a muscle is not by double and contrary movement, but only by a simple movement, there will be only one not two muscles—unless of course one should believe that the muscle operates contrary to the edicts of nature. But I would not deny that the muscle is tendonlike in the middle. This I believe serves the purpose of strengthening it and making it solid so that prevent its suffering the inconvenience of rupture—a matter worthy of some concern—during its constant movement and agitation with the arytenoid. Hence I am justified in excluding the tenth muscle from the others. Furthermore of these nine those which make up the first pair are two [musculi cricothyroides], not four as Vesallus believed (In Chapter 20 of Book II of his great work) and also Sylvius, Fuchsius and several other anatomists. They claim that these muscles regulate the movement of the shieldshape along with the cricoid. And Vesallus, an otherwise skilled and especially careful anatomist, places two pair of muscles along either side of the shieldshape on pair consist of those which verge to the front [pars recta] and II on top of each other the other pair [pars obliqua], of those which, like the intercostal muscles, intersect each other crosswise with fibers. Vesallus believed that the first of these muscles, the exterior ones, had

their origin from the lower part of the "shieldshape" and descending obliquely ran to the anterior parts of the larynx and wound their way into the unnamed cartilage [cartilago cricoidea]. The other muscles, the interior ones, are situated under these and emerge windingly from the first though in a different way. But as elsewhere quite often so in this case too Vesalius was deceived by his extreme diligence for his curiosity concerning both structure and use drove him into error. For by reason of construction or rather structure those muscles which he divides into four cannot be counted as more than two. If we are to stick to the truth of the matter. But how can we explain the mistake of so great and distinguished a man? We find this quite easy since the same error frequently happened to us. While struggling to separate the extremely thin muscles (of each kind present) we were enticed by another mistake to separate a single muscle into two sections as though it were a double muscle and subsequently we believed that there were in actual fact two muscles. But that this is mere imagination even in the case of the use of the muscle is clear from the fact that he seems to have attributed movement to the unnamed cartilage yet the actual base [cartilago cricoidea] as it were of the entire larynx completely lacks movement. For if those two muscles are attached according to his thought to the cricoid and unnamed cartilage [cartilago thyroidea], it is doubtful that they move the cricoid and unnamed cartilage—for obviously the movement of the muscle is contrary to its principle. Thus do I dispose of Vesalius' opinion on the first pair. For observation exposes only two muscles, one on each side which emerge from the lower part of the first cartilage the thyroïd, both from the outer and inner part but from the inner part the muscle emerges a little higher. Each has a wholly fleshy origin (into which the beginning of the recurrent nerves is, as a matter of fact inserted) and each tends to be broad and is triangular in shape. Furthermore these muscles provide from behind the posterior part with certain fibers descending obliquely (so that they therefore are given the name of obliquely descending muscle [pars obliqua]) then they pass rapidly to the front towards the cricoid and by pass it. Being initially broad they become thin and vice versa. Finally they push against the anterior and lateral part of the cricoid according to their various positions, and here they stop being in no part fleshy. From the above considerations it is clear that at least these muscles in the front can appropriately be called cricothyroid (as certain anatomists who delight in assigning names have decided). But when they do not start from the cricoid in the front and go to the back or go from the lower base of the thyroïd, but rather stretch from the thyroïd to the cricoid they should more accurately and correctly be called thyro-cricoids. Furthermore in animals, as for example in the cow horse and pig in our drawings, one can see it more clearly than they appear in man.

CHAPTER VI

On the Second, Third and Fourth Pairs of the Special Laryngeal Muscles

Two other muscles [musculi cricoarytenoides posteriores] follow these and make up a second pair. They seem to be almost completely united and stretched over the cricoid cartilage at their origin. Contrary to the general belief of all anatomists their origin does not start in the lower part where they make a sharp corner but in the upper part, opposite the joints of the unnamed cartilage and the arytenoid, for there it is quite clear that nerves are implanted. Joined together they emerge from the arytenoid cartilage their composition is fleshy membranous and rather strong. Advancing from there they keep on separating little by little. Verging down from above they stick closely to a long and straight rough line finally coming together again simultaneously they join each other and grow so large that they everywhere fill up the broad back aspect of the cricoid which lies near the region of the esophagus. On the basis of their configuration and position we get that elegant expression for their shape which looks almost exactly like the cow monks wear. Consequently since Realdus and other anatomists called the muscles of the shoulder-blades "monks-hoods" as a result of such a shape, we shall be allowed to give the same name to these muscles. Indeed, they look broad and oblong, even thick they are made up of various highly differentiated types of fibre and they stick to the back of the cricoid, which is very similar to the breast bone of birds on which lie the so-called pectoral muscles (which put the wings in motion like a glaucocomium [a type of pulley system]). Because of this similarity the muscles under discussion can be named the pectoral, or thoracic muscles. Yet if we examine these muscles separately when they are divided, outside their natural position and raised up, we shall, to the extent that their shape is very similar to bird wings, with great justification call them the winged muscles. This is consistent with the serious Baubinus Basillesis, anatomist and famous botanist, who called them the rear muscles of the cricoid, but not of the cricothyroid. As a matter of fact as dissection shows, arising from the arytenoid they are implanted in the cricoid, not the thyroid. But this haggling about names is pointless, for it neither adds nor detracts anything of substance. Therefore I now leave this matter and pass on to the remaining muscles. Not far from these muscles which we have already discussed, two smallish muscles can be seen which make up the third pair [musculi cricoarytenoides laterales]. A large part of them lies under the monks-hoods. They have a fleshy soft and sharp origin, and do not arise from the side of the cricothyroid, as certain

their origin from the lower part of the shieldshape and descending obliquely ran to the anterior parts of the larynx and wound their way into the unnamed cartilage [cartilago cricoidea] The other muscles, the interior ones, are situated under these and emerge windingly from the first though in a different way But as elsewhere quite often so in this case too Vesallius was deceived by his extreme diligence for his curiosity concerning both structure and use drove him into error For by reason of construction or rather structure, those muscles which he divides into four cannot be counted as more than two, if we are to stick to the truth of the matter But how can we explain the mistake of so great and distinguished a man? We find this quite easy since the same error frequently happened to us. While struggling to separate the extremely thin muscles (of each kind present) we were enticed by another mistake to separate a single muscle into two sections as though it were a double muscle and subsequently we believed that there were in actual fact two muscles. But that this is mere imagination even in the case of the use of the muscle is clear from the fact that he seems to have attributed movement to the unnamed cartilage yet the actual base [cartilago cricoidea] as it were of the entire larynx completely lacks movement For if those two muscles are attached according to his thought to the cricoid and unnamed cartilage [cartilago thyroidea], it is doubtful that they move the cricoid and unnamed cartilage—for obviously the movement of the muscle is contrary to its principle Thus do I dispose of Vesallius' opinion on the first pair For observation exposes only two muscles, one on each side which emerge from the lower part of the first cartilage the thyroid, both from the outer and inner part but from the inner part the muscle emerges a little higher Each has a wholly fleshy origin (into which the beginning of the recurrent nerves is, as a matter of fact inserted) and each tends to be broad and is triangular in shape Furthermore these muscles provide from behind the posterior part with certain fibers descending obliquely (so that they therefore are given the name of obliquely descending muscle [pars obliqua]) then they pass rapidly to the front towards the cricoid and by pass it Being initially broad they become thin and vice versa Finally they push against the anterior and lateral part of the cricoid according to their various positions, and here they stop being in no part fleshy From the above considerations it is clear that at least these muscles in the front can appropriately be called cricothyroid (as certain anatomists who delight in assigning names have decided) But when they do not start from the cricoid in the front and go to the back or go from the lower base of the thyroid but rather stretch from the thyroid to the cricoid they should more accurately and correctly be called thyro-cricoids Furthermore in animals, as for example in the cow horse and pig, in our drawings, one can see it more clearly than they appear in man

CHAPTER VII

On the Muscle of the Larynx Which Lacks a Mate

There remains the final muscle to describe. In this case it would seem especially worthwhile to consider whether this muscle should be thought of as a single or a twofold muscle [*musculus arytenoideus*]. Although Vesalius and Fuchsius are unanimous in reporting that there are two muscles, I agree with Realdus Columbus that it is only one. Unless I am mistaken the reason for their error was the peculiar shape of this muscle. For it displays two fleshy bellies and in the middle it is like a sort of thin tendon and membranous but the bellies gather them together and join them a little more tightly so that it gives the false impression of being a double muscle. However along with Columbus I have never been truly convinced that this fleshy mass, in man as well as in animals, consists of two muscles. The course which this muscle runs is as follows. It starts from the last root [*facies posterior processus muscularis*] of the one part of the arytenoid, does not arise from the length of this cartilage and after the fibres have crossed over transversely returns on a sudden to its starting point, and ends at the base of the same cartilage.¹ In the make-up of its fibres this muscle hardly differs from any of the common muscles, where they are attached to the opening. Furthermore at its point of origin and beginning, it is seen to be fleshy membranous and to a certain degree pointed from this point it approaches the middle of the cartilage transversely and proceeds while (growing) a bit more fleshy and thick after losing this thickness it swells into a belly. But you will not find it ending completely in this belly for immediately after this time it suddenly stretches further becoming broader and forming a second belly similar to the first. Then, returning to its origin, it finally ends in the middle of that cartilage from which it started. This examination concerning the course of this muscle could well raise the question why for example it is so unequal and multiform now thick, now thin then changing from one belly into two and back again into one from two. We should not bother with this sort of inquiry on the grounds that it is foreign to our treatment, for our intention at this point is to discuss structure not purposes.

Casert properly observed that the *m. arytenoid* as it is composed of both horizontal and oblique fibers; he did not, however distinguish between the separate bundles of fibers (*m. arytenoideus transversus* and *m. arytenoideus obliquus*). With this perspective, the *m. arytenoideus* would appear to the dissection to take on the shape of "bow tie" (See second facsimile diagram T but XIII *Secunda Hominis*, letter E^m of XII, XIII XV.)

The given is unclear the word opened is a translation of the Latin word *apertus*.

anatomists believe but from the arytenoid lying rather along its side for the sake of the insertion of the nerves hence they are called the muscles of the arytenothyroid or lateral muscles. From there they are carried forward a bit and become larger thicker and more teeming with flesh then they fall towards first the inner then the outer sides. At last without changing their fleshy substance they take on a thinner and more narrow pyramidal shape before disappearing into the ring like cartilage. To these oblique muscles has been entrusted the function of gently relaxing and contracting the fissure along the side (as will be evident in the proper place) After these two other muscles make up the fourth pair which link the first cartilage to the third [musculi thyroarytenoides] These are marked by a numerous variety of different fibres straight oblique rising and descending Indeed to one skilled in anatomy even they could seem more numerous. Consequently not a few anatomists have been deceived by this variety and described more muscles than is reasonable It is no surprise that certain anatomists have through inaccurate examination of the structure, even made the mistake of believing that the small upper portion of this muscle rises all the way to the base of the epiglottis This portion makes the movement which is the opposite of that made by the muscle [ligamentum hyoepiglotticum] which comes from the hyoid bone and is attached to the upper base of the epiglottis to raise it—hence it is given the name of opponent Thus four muscles are assigned to move the epiglottis—and one can hardly conceive of a more ridiculous notion since no portion of this muscle touches the epiglottis. So great then is the diversity of fibres in these muscles that unless a person brings to bear his keenest eyesight he will easily fall into error So great is their unity that he who delights in the discovery of new muscles can easily persuade himself into imagining that he has in fact discovered new muscles. A similar variety of fibres appears in the deltoid muscle [musculus deltoideus] which pulls the shoulder towards the chest and also in that very thick muscle [musculus rectus femoris] which by contracting moves one femur above the other femur That entire mass, then consists of at least two muscles, one on each side and not of more These muscles are at their origin broad fleshy continuous in turn fibrous they lie in the inner and snub-nosed middle region of the shieldshape and they run along almost its entire length by no single principle This is evident in cows because of the enormous size of those muscles in them their numerous fibrous delineations appear distinctly Gradually descending from that place as they advance posteriorly they keep growing more narrow until they are implanted along and in the side of the arytenoid These parts of the arytenoid constrict narrow and squeeze shut the fissure in the forward part [as a result of contraction by the thyroarytenoid muscle]

CHAPTER VII

On the Muscle of the Larynx Which Lacks a Mato

There remains the final muscle to describe. In this case it would seem especially worthwhile to consider whether this muscle should be thought of as a single or a twofold muscle [musculus arytenoiden]. Although Vesalius and Fuchsius are unanimous in reporting that there are two muscles, I agree with Realduus Columbus that it is only one. Unless I am mistaken the reason for their error was the peculiar shape of this muscle. For it displays two fleshy bellies and in the middle it is like a sort of thin tendon and membranous, but the bellies gather them together and join them a little more tightly so that it gives the false impression of being a double muscle. However along with Columbus I have never been truly convinced that this fleshy mass, in man as well as in animals, consists of two muscles. The course which this muscle runs is as follows: It starts from the last root [facies posterior processus muscularis] of the one part of the arytenoid, does not arise from the length of this cartilage and after the fibres have crossed over transversely returns on a sudden to its starting point and ends at the base of the same cartilage. In the make up of its fibres this muscle hardly differs from any of the common muscles, where they are attached to the opening. Furthermore at its point of origin and beginning, it is seen to be fleshy, membranous and to a certain degree pointed; from this point it approaches the middle of the cartilage transversely and proceeds while (growing) a bit more fleshy and thick; after losing this thickness it swells into a belly. But you will not find it ending completely in this belly; for immediately after this line it suddenly stretches further becoming broader and forming a second belly similar to the first. Then, returning to its origin, it finally ends in the middle of that cartilage from which it started. This examination concerning the course of this muscle could well raise the question why for example it is so unequal and multiform, now thick, now thin, then changing from one belly into two and back again into one from two. We should not bother with this sort of inquiry on the grounds that it is foreign to our treatment, for our intention at this point is to discuss structure, not purposes.

Casaeus properly observed that the *m. aryl. noddens* is composed of both horizontal and oblique fibres; he did not, however, distinguish between two separate bundles of fibres (the *m. aryl. noddens transversus* and *m. aryl. noddens obliquus*). With this perspective, the *m. aryl. noddens* would appear to the dissector to take on the shape of "bow tie" (See second (vertical) diagram Tab. in XIII *Secunda hominis*, letter F of XII, XIII, XI.)

The meaning of *noddens* (the word *nodus* in translation of the Latinized Greek *strophos*)

Since however his scruple might disturb somebody I shall offer a rather simple explanation to avoid keeping anyone in suspense any longer For the muscle under discussion is naturally so constituted for the same reason that several other muscles appropriate two bellies The muscle which moves the lower jaw downwards [*musculus digastricus*] and also that oblong muscle [*musculus omohyoideus*] which comes from the shoulder blade to the hyoid bone are both provided with two bellies Thus they are made stronger by their own tendon from whose intermediate position the bellies are formed and resist more vigorously the powerful motion of the jugular artery (carotid) For if they had been completely of fleshy substance nature would have displayed too little concern for them The same reason applies to the two bellies of our muscle For since the little fissure which the third cartilage makes, constantly moves the muscles about the middle by dilation and contraction and stirs them in its marvellous way the muscle has been made of tendons and flesh in order to resist (especially during suspension of breathing) those violent movements and avoid splitting And to prevent this muscle from being in the way due to too large a mass or the movement of that cartilage nature in her full wisdom has made it quite small For so small is the muscle that it is considered the tiniest of all the muscles in the entire body And when it constricts the larynx with might, it opposes the action of many muscles—which seems indeed a thing of wonder

It displays a semi-circular shape This shape is the true structure and description of the laryngeal muscles this is their true number They are in my opinion fixed at thirteen not fourteen (as Realdus and Fallopius claimed) not twenty (as Vesallus believed) and not eighteen (as Fuchsius said) Of these thirteen there are four pairs of laryngeal muscles proper a single muscle without a mate (hence the term *unwedded*) and two pairs of common muscles.

CHAPTER VIII

On the Recurrent Nerves

Now that I have completed the investigation of the laryngeal muscles, my enthusiasm demands that I take up in my discussion a description of the nerves which impart to the muscles the ability to move. In my description of these nerves, drawings of great clarity shall reveal nature's enormous skill, the industry of the great Artificer and also a virtually incredible piece of handiwork. For the nerves have been constructed by the benign parent of all things, God and Nature in so marvellous a fashion that I cannot fail to be astounded at the many rash judges who did not blush at accusing the second one the mother of all things, of a want in skill and at calling her a step-mother. For a man of dullest intellect will be able to ascertain her forethought and cleverness. These nerves run as follows: some wind along transversely some obliquely some downwards after starting upward and vice versa, some to the left, others to the right, and finally enter the muscles. And the reason? They run by such a varied course because of the position of the muscles which they pass under. For the nerves cannot be inserted to any part of a muscle but either to its head alone, or its middle (commonly called the belly) but below the middle for example at the end or tendon they can never be implanted, since on contraction of the fibres the beginning of the muscles would approach the condition of the end. For all muscles are constantly contracted towards their origin provided that they are supplied with shoots of nerves. Since then, only one insertion or the other of the nerves to the muscles is possible it was necessary for them to run in so varied a fashion. Anatomy teaches that some of the muscles have a transverse position, more have an oblique position, the rest a straight position according to whether they look up from below or down from above. Two nerves [nervus laryngeus superior], looking down from above, wind into two laryngeal muscles [musculi cricothyroides] by way of two offshoots. One of these outgrowths, stretching towards the broader part of the thyroid (shield shape) cartilage is attached to it the other one runs along the oblique muscles and those muscles which are stretched to the pectoral bone. Just as these two muscles [musculi cricothyroides] descend from above, so also the two nerves which advance to the position of the muscles are formed for their sake. Just as the muscles which look upwards from below [musculi sternothyroides] are set over against the former muscles, so it was necessary for the nerves to be channelled from the lower parts to the upper. Since, however, all the nerves emerge from the neck or the spinal medulla, it will be pertinent to inquire first from what beginning the nerves that are scattered throughout the larynx take their origin, and secondly how they are implanted into the muscles. It is not reasonable for them to proceed from

the neck or the cervical spinal medulla since then they would be destined to be oblique And even if this objection is removed, still it would be reasonable for nature to share the nerves not from the most worthless origin of the nerves, but from their more worthy one namely the larynx which is the chief organ of voice Therefore consider the brain The nerves which originate in the brain emerge from two mutually distinct and separate sources, inasmuch as they come from the sixth [N IX X XI] or seventh [N XII] pairs From those of the seventh pair they could not possibly spread forth since they would be completely useless, being as it were oblique Therefore, clearly they come from those nerves of the sixth pair These nerves run straight down through the neck along either side of the trachea and advancing a little from their point of emergence they immediately scatter into many branches. Some of them creep to the chest heart lung stomach others go further and advance to the belly liver spleen and almost all the parts contained in the abdomen Indeed since they cannot stretch from the straight advance of the nerves from above to the lowest parts, to the laryngeal muscles either laterally or obliquely nature the doer in her cleverness and amazing foresight discovered a most suitable aid for the requisite action From the nerves which continue on to the chest she makes a double branch one on each side return by the same path they went down Of these the right branch, being higher than its mate is supported and enfolded by that branch [arteria subclavia] of the great artery [truncus brachiocephalicus] which proceeds to the right arm The left one being much lower than the former winds around the trunk of the greatest artery [arcus aortae] where it curves back and descends then bending back slightly it suddenly creeps upwards along the same path winding skillfully into the inferior muscles of the larynx Similarly in the case of drawing off water from its source by canals, (man's) art separates them off to the sides, up down in front behind obliquely or hither and thither through ascent and descent Moreover when the nerves are moved towards their origin which they take from the brain or the beginning of the medulla a contraction toward the lower parts, near the trunk of the large artery will take place through motion of the recurrent nerves which are inserted into the lowest muscles of the larynx When the nerves from which branch those notable offshoots in remarkable looping are moved a pulling from below upward to the head will take place When near the head contrary motions of the sixth pair and the recurrent (nerves) succeed each other that movement is neatly represented as corresponding to metaleptic or transumptive motion Metaleptic motion is that which mechanical laborers, as well as the doctors named organici employ in the instrument which is properly called *glossocomium* By means of this instrument doctors restore with the great

est ease and calm, people whose legs and arms run riot to their former place. The construction of this machine is as follows: its top and bottom sections contain a plank, and on the machine several little pulleys are built up. To these pulleys is tied in criss-cross fashion a series of snoods. Now when doctors plan to use it, for example, to reset dislocated bones, they encircle the broken limbs with ropes that hang down from the *glossocomium* and by a gentle tightening of the ropes a tension in either direction up and down, is effected, which is suitable and correct for the affected limbs. In these movements lies what we are calling metaleptic motion. Hence it is clear that metaleptic motion consists of raising and lowering, whether in elevation or depression, and of contrary but simultaneous motions of the same thing. Our mind hasn't the power even to conceive that this motion can be effected without the pulleys. Therefore Avicenna rightly denied that the motion of ascent and descent, arising at one and the same time in one situation, could take place unless there should be present something resembling the *gyrgillus* above which the revolving and circling is carried on. *Gyrgillus* is the proper designation for the little wheel, or instrument, by means of which spinning women roll up their thread, and it is perhaps so called from the fact that it spins around. Quite similar is the *trochlea* (type of pulley system) or *orbiculus striatus* (disk) made of wood or bronze by means of which water is scooped from a well as a connecting rope is lowered and raised. But now we must elucidate more thoroughly the system of recurrent nerves and reveal more abundantly the power, wisdom and providence of the Great Artificer (to which Galen bears brilliant and marvellous testimony in the seventh book, chapter 14, of *De Usa Partium*) therefore it is fitting to compare to this artificial transumptive motion the motion of the recurrent nerves by which they are moved towards their first origin. Is it not the case that in artificial metaleptic motion the origin of motion starts around the axis of the instrument known as *Glossocomium*? Further that the supports or appendices of the net are stretched all the way to the pulleys. For a noose is most suitable for this purpose—that is, a noose which consists of two appendices. Indeed, at least some older writers called it The Wolf perhaps because it had four limbs (supports). Is it not possible to see the same thing in the movement of the so-called recurrent nerves while they are being moved from their own origin. Instead of the plank there is the brain, from which the nerves come forth and the nerves are like the noose. Furthermore as in the case of that pulley along which the noose curves as it is twisted into a spiral, doesn't it play the same role as the artery around which the nerves are twisted? For this reason it is called the turning post, or *kimpter* in Greek. In the cow and horse the shield-shape is like the pulley and at its upper tip some offshoots of the recurrent nerves are seen to come out through certain sculpted apertures.² Consider also that where the recur-

² That branch of the recurrent nerve (which we distinguish today as the *N. laryngeus superior*) enters the shield-shape (*cartilago thyroidea*) at the second metaleptic point of the machine.

the neck or the cervical spinal medulla since then they would be destined to be oblique. And even if this objection is removed, still it would be reasonable for nature to share the nerves not from the most worthless origin of the nerves, but from their more worthy one namely the larynx, which is the chief organ of voice. Therefore consider the brain. The nerves which originate in the brain emerge from two mutually distinct and separate sources, inasmuch as they come from the sixth [N IX N XI] or seventh [N XII] pairs. From those of the seventh pair they could not possibly spread forth since they would be completely useless, being as it were oblique. Therefore clearly they come from those nerves of the sixth pair. These nerves run straight down through the neck along either side of the trachea, and advancing a little from their point of emergence they immediately scatter into many branches. Some of them creep to the chest, heart, lung, stomach others go further and advance to the belly, liver, spleen and almost all the parts contained in the abdomen. Indeed since they cannot stretch from the straight advance of the nerves from above to the lowest parts, to the laryngeal muscles either laterally or obliquely, nature the doer in her cleverness and amazing foresight discovered a most suitable aid for the requisite action. From the nerves which continue on to the chest she makes a double branch, one on each side return by the same path they went down. Of these the right branch being higher than its mate is supported and enfolded by that branch [arteria subclavia] of the great artery [truncus brachiocephalicus] which proceeds to the right arm. The left one being much lower than the former winds around the trunk of the greatest artery [arcus aortae] where it curves back and descends then bending back slightly it suddenly creeps upwards along the same path winding skillfully into the inferior muscles of the larynx. Similarly in the case of drawing off water from its source by canals, (manus) art separates them off to the sides, up down in front behind obliquely or hither and thither through ascent and descent. Moreover when the nerves are moved towards their origin which they take from the brain or the beginning of the medulla a contraction toward the lower parts, near the trunk of the large artery will take place through motion of the recurrent nerves which are inserted into the lowest muscles of the larynx. When the nerves from which branch those notable offshoots in remarkable looping are moved a pulling from below upward to the head will take place. When near the head contrary motions of the sixth pair and the recurrent (nerves) succeed each other that movement is neatly represented as corresponding to metaleptic or transumptive motion. Metaleptic motion is that which mechanical laborers, as well as the doctors named *organici* employ in the instrument which is properly called *glossocomium*.¹ By means of this instrument, doctors restore with the great

or two fingers squeeze them, the voice is lessened. If the nerves are tied or split, the voice is not only lessened, but completely disappears. If they are cut off the animal will continue on through life mute. But if they are first tied and then undone again the tone of these nerves returns and is one and the same for all other nerves, in as much as they take on the appearance of the constituent nerves. It should, however be observed that they differ considerably in quality according by degrees: some are more moist than others, some dryer, some softer and some harder. Furthermore they are everywhere of consistent constituency: for example the trunks of the nerves are like the substance of their origins. So the nerves of the brain (which consists of three parts—two membranes and a medullary body) and also of the larynx resemble in substance their trunks, and therefore the origins of their trunks. They are quite small and slight so that they deceptively escape our eyes. The quantity of muscles, however, in which they are inserted demanded such nerves, for the nerves must necessarily correspond in a certain proportion to those muscles. Yet their number is not infinite, if indeed (in Galen) the two recursive nerves are made up of the nerves which ascend to the larynx: these two emerge from two branches of the sixth pair of nerves that start closest from the brain. Their shape to be once more repetitive is curved backwards and ring like so that they are called reflex, the recurrent and recursive. The connection is obvious from what I have said.

rent nerves ascend the artery is firm stable and smooth not rough, unequal or moveable that it sits not just anywhere but in a due and proper place just as the pulleys which being firm stable and smooth not rough or unequal fittingly have been placed not just anywhere but in a fixed determined and most suitable place For so they ought to have been constructed and shaped Consequently neither the clavicles nor the bones or ribs or anything else of the chest's multitudinous content could be suitable for discharging such a function For although there are some of them which are firm not rough and not unequal these are not at all situated in a place suitable for nerves rather they lie on the external part which is full of danger and from which nerves shy away strongly And that for a simple reason being exposed to harm those very delicate bodies would be removed from nature's right state and position Therefore since nerves must shoot off far and wide to all the muscles of the entire body in order to provide them with motion and sensitivity and since just as the soul is directed through their agency as a horse is by reins and bridle so it could at will move and pull hither and thither the most distant parts of the body—(because of this) nerves advance flowingly obliquely transversely and by varied and multiform steps for their greater safety And the further nerves are from their point of origin and branching the more is their strength increased For since the origins of nerves are quite moist and soft the closer they are to the brain their prodigal source the more moist and soft and hence weaker is the nature which they acquire On the other hand the farther they are from the brain the more they grow dry and hard, and thus become stronger Indeed the warmer the places and paths are which they pass through the greater is the dryness and hardness which they take on and the greater the strength which accrues to them Thus the artery and heart impart much dryness and hardness to them Everyone realizes how much usefulness and suitability is imparted to the nerves as they advance further and also how much protection and safety there is for the recurrent nerves because they are rather distant from their beginning

But let me now return to the point where the digression began In transumptive motion the noose was adapted to the pulley around which it runs, and a limb properly attached to the extensions of the noose undergoes opposite motions at one and the same time one section being pulled up and the other down so in natural motion the nerves which being attached to and resting on the artery they turn around are inserted into the muscle sustain an up and downward motion at one and the same time For this reason Galen in the fourth (book) sixth chapter of *De Loc Affect* calls them current or recurrent and recursive because like horses on the fields they run back and forth Because of this motion they are called *regressive* by Avicenna But they also deserve to be called the *vocal nerves* since they provide the ability and breath necessary to modulate the voice If anybody should doubt this, he should handle these nerves in various ways in his hands Then he would observe that various differences of pitch arise If one

or two fingers squeeze them, the voice is lessened. If the nerves are tied or split, the voice is not only lessened, but completely disappears. If they are cut off the animal will continue on through life mute. But if they are first tied and then undone again the tone of these nerves returns and is one and the same for all other nerves, in as much as they take on the appearance of the constituent nerves. It should, however be observed that they differ considerably in quality according by degrees some are more moist than others, some dryer some softer and some harder. Furthermore they are everywhere of consistent constituency for example the trunks of the nerves are like the substance of their origins. So the nerves of the brain (which consists of three parts—two membranes and a medullary body) and also of the larynx resemble in substance their trunks, and therefore the origins of their trunks. They are quite small and slight so that they deceptively escape our eyes. The quantity of muscles, however in which they are inserted demanded such nerves, for the nerves must necessarily correspond in a certain proportion to those muscles. Yet their number is not infinite, if indeed (in Galen) the two recursive nerves are made up of the nerves which ascend to the larynx. These two emerge from two branches of the sixth pair of nerves that start closest from the brain. Their shape to be once more repetitive is curved backwards and ring like, so that they are called reflexive recurrent and recursive. The connection is obvious from what I have said.

INTRODUCTION

Acute chronic and recurrent suppurative otitis media have long been recognized as major health problems of the aboriginal people of Alaska, particularly those living in the isolated village environment out of reach of prompt medical attention. It was not until completion of a survey conducted in 1936 by consultants to the Alaska Department of Health, under the sponsorship of the U.S. Children's Bureau, that a statistical appraisal was made of the epidemiological and clinical magnitude of this problem (1, 2). A total of 899 individuals was examined: 84% under 20 years of age. Of the Eskimos examined, 33% had significant hearing loss and 57.9% had lesions of the tympanic membrane. Among Indian subjects, 23.3% had significant hearing loss and 43.5% had lesions of the tympanum such as perforation, scarring, retraction or inflammation due to previous or existing otitis media. Mastoidectomy was recommended urgently for 3.9% of all the subjects examined. Prophylactic removal of tonsils and adenoids was recommended for 41.2% of the children examined with view of reducing the prevalence of otitis and mastoiditis. The survey team estimated that among the children and youth of the Eskimo population alone 739 persons (37.4%) were in need of mastoidectomy and that prophylactic removal of tonsils and adenoids might be indicated for 2785 persons (14.1%).

Following the 1936 survey the Alaska Department of Health and Welfare with the assistance of the U.S. Children's Bureau, conducted a study aimed at demonstrating ways of reducing the prevalence of acute and chronic otitis media. This was carried out in six villages in the Yukon-Kuskokwim delta region, between September 1957 and September 1959. The study demonstrated, when analyzed and summarized (3) that the aggressive case finding, rigorous therapy and relevant health education, were indeed followed by a reduction in the prevalence of otitis and tympanic membrane damage and an apparent general improvement in child health.

The Infectious Disease Program of the Arctic Health Research Center Public Health Service joined forces with the agencies mentioned above to provide a microbiological phase to the study. The immediate service objectives were to conduct expeditious virological and bacteriological culture of specimens taken from cases of otitis and to determine the antibiotic sensitivities of each kind of bacteria isolated from each case. The bacteriological results were forwarded as soon as possible to the field teams to allow adjustment of antibiotic therapy to the kinds of bacteria found in each case. The investigational objectives of the microbiological work were to gain information on the types of infectious agents associated with otitis media in Alaskan

native people. The objectives were also aimed at gaining some concepts of the change in the microbiology of otitis media with persistence of infection. Such information was considered to be of potential practical value to physicians faced with determining rational chemical or antibiotic therapy of otitis media in clinical situations when bacteriological diagnostic services were not available. Another aim of the microbiological study was to determine whether antibiotic therapy or prophylaxis might be in itself a determinant of the sequence of microbiological events in persistent otitis media.

CHARACTERISTICS OF POPULATION STUDIED

According to the final report of the demonstration project (3) the villages studied ranged in population from 116 to 240 with a total of 1009. Of these 546 individuals were under 17 years of age. In the group under 17 years 36.1% were Eskimo, 27.8% Indian, 26.4% of mixed racial origin, 5.9% Caucasian and 3.8% undefined. In age 6.4% of the children of the villages were under 1 year of age, 30% 1 to 4 years, 33.9% 5 to 9 years and 29.7% 10 to 14. Relatively reliable and precise information on chronology and duration of otitis was available on 130 individuals. Of these 118 were under 15 years of age. Table 1 shows their distribution by village and by age group. This table shows the seriously high prevalence of otitis among the younger age groups. The distribution by village shows great variation in prevalence of otitis. These villages were ethnically and socioeconomically dissimilar; therefore these factors could account for the disparity of distribution of otitis among them.

DISTRIBUTION OF CASES BY AGE OF ONSET AND CHRONICITY

Of the 130 persons studied microbiologically the age at onset of otitis ranged from 2 to 360 months, with an arithmetic mean of 52 months. Thirty-five percent of these subjects had developed suppurative otitis media with perforation of the tympanum by 1 year of age, 52% (cumulatively) before 2 years of age. Thirty-eight percent of the subjects developed otitis between 2 and 10 years of age and only 10% after 10 years.

SAMPLING METHODS AND MATERIALS

The procedures and conditions of microbiological sampling were governed by the practical objectives of the study-demonstration and the field working conditions. Since the primary study objectives were casefinding and expedi-

TABLE 1 Age distribution of study population and otitis cases.

A. By Age Group

Age	Total no. in age group in villages studied	Number of otitis cases studied bacteriologically	% Age group with otitis
Under 1 year	35	16	45.7
1 to 4 years	184	55	33.5
5 to 9 years	183	31	16.4
10 to 14 years	102	13	8.0

In addition, 2 of the subjects were in the 15- to 19-year-old age group, 3 in the 20- to 24-year group and 1 over age 25.

tious initiation of medical treatment, only the initial cultures from each case represented natural infectious flora. All subsequent or "Following" cultures were made after the subjects had been given courses of sulfonamide or antibiotic agents as well as other therapeutic treatment. The working conditions of field clinical operations did not allow sampling of acute otitis media exudate before pathologic perforation of the tympanum. Therefore none of the microbiological work reported here is equivalent to the fine investigations of Lahtikainen (4) and Grönroos and associates (5) who obtained specimens of acute otitis media exudate by needle aspiration through the unruptured tympanic membrane. Likewise the itinerant character of our field operations did not allow on-site bacteriological culture of samples, but required that specimens be forwarded by air transport to the central laboratory. The methods for transmission of samples are described in a following section of this paper.

To test the relationship between pharyngeal flora and that of otitis exudate the field staff was requested to obtain a throat swab sample whenever feasible to accompany the swab specimen of ear exudate from each case. Although this was not accomplished in all cases, sufficient numbers of paired ear exudate and throat swab specimens were obtained to allow comparisons of flora from the two sites, and to study the comparative change in flora with continuation of infection.

To obtain specimens of ear exudate the field staff was instructed to clean the external auditory canal with sterile cotton swabs, without use of anti-

septica, until it was free of crusted old exudate. Then fresh exudate was taken with a sterilized cotton tipped applicator stick. The applicator was then inserted in transmission medium for forwarding to the laboratory. To obtain samples of pharyngeal flora the lateral walls, the tonsils, and the posterior wall of the pharynx were swabbed with a sterilized cotton tipped applicator. The applicator tip was then plunged into transmission medium for forwarding to the laboratory.

Transmission medium for bacteriological culture was a buffered agar containing heart infusion, proteose-peptone, gelatin, dextrose and casein (Stock Culture Agar Difco). This was tubed, as a butt about 5 cm in depth, in screw cap glass vials or plastic friction seal vials. This medium was used in preference to a fluid or semisolid medium to prevent leakage in transit and the consequent intrusion of bacterial contamination through the closure. Transmission medium for virological specimens was Earle's balanced salt solution with addition of calf serum to the concentration of 1%. The medium contained sufficient amounts of penicillin, streptomycin and nystatin to prevent bacterial and fungal growth. Later in the study 1% gelatin also was added to assist in viral stabilization. This medium was found in other studies to be adequate as a sample transmission and maintenance medium for influenza virus, poliovirus, ECHO viruses, Coxsackie viruses and adenovirus. The virological medium was tubed in 2 ml amounts in screw cap glass vials.

The field staff was instructed to keep bacteriological samples at approximately 10 C and to keep the virological samples as cold as possible without freezing until the time of forwarding. These conditions could easily be approximated in the customary village habitation by keeping the bacteriological specimens on the floor in living quarters, away from the radiant heat of stoves, and the virological specimens within insulated containers in the storm shed.

These methods of sample maintenance and transmission had been tested previously by the senior author in other field operations and found to be efficacious. In those field tests, comparison of bacteriological cultures made on site in the village and cultures made at the central laboratory one to two weeks later from simultaneously taken samples kept in transmission medium showed excellent preservation of flora in kind and quantity. The virological sampling and transmission methods were also found adequate in other projects, to allow cultivation in the central laboratory of viruses as fragile as influenza which had been obtained from cases in remote sites several days previous to initiation of culture in the central laboratory. These virological methods were nevertheless, inadequate for organisms such as the Respiratory Syncytial Virus which with current sampling and cultural systems, require immediate cultivation.

MICROBIOLOGICAL CULTURE METHODS

The cultural approaches and procedures were selected and devised to serve both the practical objectives of providing the field physician with early bacteriological advice and the research objectives of determining, to the greatest degree practicable, the genera and species of bacteria associated with purulent otitis media. Maximum utilization of limited laboratory facilities and personnel required a highly systematized cultural regimen. The same limitations prevented the inclusion of additional bacteriological examinations for genera or species of special interest such as anaerobic cocci, mycobacteria, or pleuropneumonia like organisms. The methods were competent to obtain pure cultures and identify about 90 species of aerobic bacteria, belonging to 23 genera, distributed among the families *Pseudomonadaceae*, *Achromobacteraceae*, *Enterobacteriaceae*, *Micrococcaceae*, *NesERIaceae*, *Lactobacillaceae* (tribe *Streptococceae*) and *Corynebacteriaceae*. The scheme of morphological and biochemical tests was developed according to Bergey's Manual (6) except for the *Streptococci* which were identified according to the classification of Sherman (7). The scheme required the employment of 32 different morphological or biochemical determinations. The least number of tests required for classification within any one family was 10 (*NesERIaceae*) the most, 19 (*Enterobacteriaceae*). In addition, hemolytic streptococci were classified antigenically by the Lancefield precipitin method.

Antibiotic sensitivity determinations were made with the use of "Bacto Unidisks" (medium concentration). The type of disks used included Penicillin (6 units), Chloromycetin (10 mcg), Tri Sulf (150 mcg), Terramycin (10 mcg), Tetracycline (10 mcg), Erythromycin (5 mcg), Dihydrostreptomycin (5 mg) and Aureomycin (10 mcg). Late in the study when the field physician introduced Neosporin into the therapeutic array Neomycin (10 mcg) and Polymyxin (100 units) sensitivity discs were added to the array. Antibiotic sensitivity tests were carried out on poured agar plates inoculated heavily with the test organisms, according to procedures recommended by the manufacturer. In our tests only the medium level of concentration of each antibiotic was used, since the readings were comparative among many bacterial isolates. The laboratorians carrying out the sensitivity determination standardized their readings by frequent independent dual readings of tests and agreed on a reading of "very sensitive" for an inhibition zone greater than 0.7 cm, "moderately sensitive" for an inhibition zone of 0.25 to 0.7 cm and "slightly sensitive" for an inhibition zone of 0.25 cm or less. Organisms which grew to the edges of and under the antibiotic disks were considered "resistant". This type of sensitivity determination was considered to be only roughly quantitative but adequate to assist the field physician in making rational selection of antibiotics for continued treatment of the individuals under study.

The general bacteriological approach was as follows. Each swab received for culture was streaked on a plate of stock culture agar enriched with 10% whole blood (human, type O) and incubated at 37 C for 24 to 72 hours, depending on the time required to obtain good growth of colonies. Representative colonies of each type present on each plate were picked and streaked on stock culture agar slants. If indicated by the nature of the growth serum agar or blood agar slants were used for growing stock of specific isolates. After morphological and microscopic observation to check on purity (mixed cultures were restreaked on plates for separation) antibiotic sensitivity determinations were made of each isolate and a transplant was made to provide stock for later taxonomic determinations. Thus gross morphologic classifications (gram negative rod streptococcus, micrococcus, etc.) and antibiotic sensitivity determinations on all of the isolates from a group of specimens were usually accomplished within 6 days of receipt of the specimens, and the results forwarded to the field clinical staff. Taxonomic work on the isolates was carried out as time permitted.

Virological specimens were cultured in tissue culture (monkey kidney and Kb cells) suckling mice and embryonated chicken eggs. The techniques used in tissue culture and suckling mouse inoculations have been described in a previous publication (8). The chick-embryo cultures employed eggs incubated for seven days previous to inoculation. These were infected sub-allantoically with specimen fluids. The eggs were examined by transillumination daily after inoculation. Moribund embryos were harvested as soon as they were detected. All remaining embryos were harvested at 7 days incubation after inoculation. A second passage of ground amnion and allantoic membrane from the embryos inoculated initially was made to allow additional opportunity for viral propagation. At harvest both embryos and membranes were examined grossly for evidence of pathology. Allantoic and amniotic fluids from each egg passage and fluids from each tissue culture passage were harvested and tested for hemagglutinating agents.

GENERAL RESULTS AND ANALYSES

None of the virological specimens cultured in any of the media used yielded viral isolates. Since in other work on different disease and ecological issues, a wide variety of enteric viruses, adenoviruses and reoviruses had been recovered by similar sampling and identical laboratory techniques, we concluded that such viruses were not present in the stool exudate of the cases studied. We could not conclude the same with respect to agents such as the Respiratory-Syncytial Virus, which require immediate cultivation.

Since a primary objective of this study was to determine the changes in flora with duration of illness, the subject cases were classified into eight groups according to time elapsed between initial occurrence of symptoms

TABLE 2. Isolate-Sample ratio of cultures obtained from otitis exudate

Group	Ratio ^a Initial cultures	Ratio ^a Following cultures (Persistent cases)
I	2.5	3.3
II	3.3	4.2
III	2.5	2.5
IV	1.7	2.8
V	1.5	2.5
VI	2.4	3.5

Overall	2.3	3.1

$$\text{Ratio} = \frac{\text{Total number of bacterial isolates from group}}{\text{Total number of samples in group}}$$

and the first sampling for microbiological culture. These groups, their chronological characteristics and size are as follows

- Group I, duration of otitis 1 week or less, 21 individuals
- Group II, duration of otitis 1 week to 1 month, 16 individuals
- Group III, duration of otitis 1 month to 6 months, 19 individuals
- Group IV, duration of otitis 6 months to 1 year, 23 individuals
- Group V, duration of otitis 1 year to 2 years, 14 individuals
- Group VI, duration of otitis 2 years to 5 years, 13 individuals
- Group VII, duration of otitis 5 years to 10 years, 13 individuals
- Group VIII, duration of otitis over 10 years, 11 individuals

In earlier phases of data analysis, the individuals of Group III had been divided into two groups, one with otitis duration of 1 to 2 months, and the other 2 to 6 months. However no significant difference between them was found in the kind and prevalence of bacterial species; therefore, they were combined into one group for the final analysis.

Although a wide variety of bacterial species and types were encountered, no one specimen yielded a large number of isolates. Table 2 summarizes the rate of isolates per sample in the Initial and Following cultures. Each morphologically distinct colony type on each culture plate was picked for identification, but in a large number of instances the taxonomic determinations indicated that colonial variants of the same species had been recovered. These were counted as a single species isolation.

The maximum time interval between the Initial culture and last Following culture serves as a measure of persistence or recurrence of exudative otitis in the cases under study. The case-distribution by maximum interval is given for each group in Table 3.

In 5% of the cases, otitis did not persist beyond four months after

and the first sampling for microbiological culture. These groups, their chronological characteristics and size are as follows:

- Group I, duration of otitis 1 week or less, 21 individuals
- Group II, duration of otitis 1 week to 1 month, 16 individuals
- Group III, duration of otitis 1 month to 6 months, 19 individuals
- Group IV, duration of otitis 6 months to 1 year, 23 individuals
- Group V, duration of otitis 1 year to 2 years, 14 individuals
- Group VI, duration of otitis 2 years to 5 years, 12 individuals
- Group VII, duration of otitis 5 years to 10 years, 13 individuals
- Group VIII, duration of otitis over 10 years, 11 individuals

In earlier phases of data analysis, the individuals of Group III had been divided into two groups, one with otitis duration of 1 to 2 months, and the other 2 to 6 months. However, no significant difference between them was found in the kind and prevalence of bacterial species; therefore they were combined into one group for the final analysis.

Although a wide variety of bacterial species and types were encountered, no one specimen yielded a large number of isolates. Table 2 summarizes the rat. of isolates per sample in the Initial and Following cultures. Each morphologically distinct colony type on each culture plate was picked for identification, but in a large number of instances the taxonomic determinations indicated that colonial variants of the same species had been recovered. These were counted as a single species isolation.

The maximum time interval between the Initial culture and last Following culture serves as a measure of persistence or recurrence of exudative otitis in the cases under study. The case-distribution by maximum interval is given for each group in Table 3.

In 8% of the cases, otitis did not persist beyond four months after

The general bacteriological approach was as follows. Each swab received for culture was streaked on a plate of stock culture agar enriched with 10% whole blood (human type O) and incubated at 37 C for 24 to 72 hours, depending on the time required to obtain good growth of colonies. Representative colonies of each type present on each plate were picked and streaked on stock culture agar slants. If indicated by the nature of the growth serum agar or blood agar slants were used for growing stock of specific isolates. After morphological and microscopic observation to check on purity (mixed cultures were restreaked on plates for separation) antibiotic sensitivity determinations were made of each isolate and a transplant was made to provide stock for later taxonomic determinations. Thus gross morphologic classifications (gram-negative rod, streptococcus, micrococcus, etc.) and antibiotic sensitivity determinations on all of the isolates from a group of specimens were usually accomplished within 6 days of receipt of the specimens, and the results forwarded to the field clinical staff. Taxonomic work on the isolates was carried out as time permitted.

Virological specimens were cultured in tissue culture (monkey kidney and Kb cells) suckling mice and embryonated chicken eggs. The techniques used in tissue culture and suckling mouse inoculations have been described in a previous publication (8). The chick-embryo cultures employed eggs incubated for seven days previous to inoculation. These were injected suballantoically with specimen fluids. The eggs were examined by transillumination daily after inoculation. Moribund embryos were harvested as soon as they were detected. All remaining embryos were harvested at 7 days incubation after inoculation. A second passage of ground amnion and allantoic membrane from the embryos inoculated initially was made to allow additional opportunity for viral propagation. At harvest both embryos and membranes were examined grossly for evidence of pathology. Allantoic and amniotic fluids from each egg passage and fluids from each tissue culture passage were harvested and tested for hemagglutinating agents.

GENERAL RESULTS AND ANALYSES

None of the virological specimens cultured in any of the media used yielded viral isolates. Since in other work on different disease and ecological issues, a wide variety of enteric viruses, adenoviruses and myxoviruses had been recovered by similar sampling and identical laboratory techniques, we concluded that such viruses were not present in the otitis exudate of the cases studied. We could not conclude the same with respect to agents such as the Respiratory-Syncytial Viruses, which require immediate cultivation.

Since a primary objective of this study was to determine the changes in flora with duration of otitis the subject cases were classified into eight groups, according to time elapsed between initial occurrence of symptoms

TABLE 2. Isolate—Sample ratio of cultures obtained from otitis exudate

Group	Ratio ^a Initial cultures	Ratio ^a Following cultures (Persistent cases)
I	2.6	3.3
II	2.3	4.2
III	2.6	2.6
IV	1.7	2.4
V	1.6	2.9
VI	2.1	3.6
VII	2.3	2.9
VIII	2.1	2.9
Overall	2.3	3.1

$$\text{Ratio} = \frac{\text{Total number of bacterial isolates from group}}{\text{Total number of samples in group}}$$

and the first sampling for microbiological culture. These groups, their chronological characteristics and size are as follows:

- Group I, duration of otitis 1 week or less, 21 individuals
- Group II, duration of otitis 1 week to 1 month, 16 individuals
- Group III, duration of otitis 1 month to 6 months, 10 individuals
- Group IV, duration of otitis 6 months to 1 year, 23 individuals
- Group V, duration of otitis 1 year to 2 years, 14 individuals
- Group VI, duration of otitis 2 years to 5 years, 13 individuals
- Group VII, duration of otitis 5 years to 10 years, 13 individuals
- Group VIII, duration of otitis over 10 years, 11 individuals

In earlier phases of data analysis, the individuals of Group III had been divided into two groups, one with otitis duration of 1 to 2 months, and the other 2 to 6 months. However, no significant difference between them was found in the kind and prevalence of bacterial species; therefore, they were combined into one group for the final analysis.

Although a wide variety of bacterial species and types were encountered, no one specimen yielded a large number of isolates. Table 2 summarizes the rate of isolates per sample in the Initial and Following cultures. Each morphologically distinct colony type on each culture plate was picked for identification, but in a large number of instances the taxonomic determinations indicated that colonial variants of the same species had been recovered. These were counted as a single species isolation.

The maximum time interval between the Initial culture and last Following culture serves as a measure of persistence or recurrence of exudative otitis in the cases under study. The case-distribution by maximum interval is given for each group in Table 3.

In 76% of the cases, otitis did not persist beyond four months after

TABLE 3 *Percentage distribution of cases by interval between first and last culture*

treatment was initiated. Groups I, II, and VIII showed the lower rates of persistence of infection beyond four months, while Groups III, V, and VII had the higher. No infections in Groups I and II were found beyond 12 months after initial culture, while in Groups III, IV, VI, and VII cases with purulent exudate were found 18 to 21 months after initial diagnosis. The data indicate that infections which have been established a month or more before treatment is begun are more likely to be resistant to therapy than those infections which are treated at an earlier stage. This is not a new thought. The data merely underscore the accepted desirability of early diagnosis and treatment. Nevertheless it is encouraging to note that even with cases that had been chronic or recurrent over a number of years, treatment to the extent allowed by itinerant nursing and medical services led to remission of the large majority of cases within a few months.

It is of pathogenetic significance to know the anatomic extent of involvement. Accordingly we determined whether the involvement was unilateral or bilateral at the time of initial sampling. The same was tabulated for the following cultures on cases which were recurrent or chronic. Table 4 summarizes the findings.

Table 4 presents some interesting variations, from group to group with regard to the anatomic involvement. But no distinct pattern is discernible except that at least a third of the patients with persistent purulent perforating otitis had bilateral involvement within a few months, including some of those treated within one week of onset of symptoms. The cases with eventual bilateral involvement comprised a large majority of the persistent or recurrent cases. This is deduced from comparisons of the data of Tables 3 and 4.

RESULTS—BACTERIOLOGICAL

The taxonomic identification of several thousand isolates of "wild" bacterial strains is an exercise in judgement and interpretation rather than that of mechanical adherence to precise criteria. In many instances the taxonomic determination made upon the basis of the morphological and biochemical characteristics of an isolate was that of "most probable species." Occasionally an isolate could be assigned to a genus, but would not fit most of the criteria for any one species. In such a case the species was left undetermined. With certain genera such as *Achromobacter* or *Flavobacterium*, which were generally of very low prevalence, no attempt was made to determine the species of the isolate. Our experience with taxonomic identification of wild strains is not unique. Indeed, taxonomic problems are to be expected in large scale isolation and identification of asprophytes which are facultatively and incidentally pathogenic.

Various modes of statistical representation of the microbial flora in otitis were tried. We found that analysis by case-prevalence was the more relevant to our epidemiologic and ecologic objectives. It was considered to be more important that we should determine the probability of occurrence of a species in a given class of cases of otitis than to determine the relative importance of a species in relation to all other bacterial species encountered in otitis. Furthermore in comparison of prevalences among species, case prevalence was considered to be a more absolute measure of their patho-ecologic importance.

Except for the *Streptococci* (particularly in pharyngeal cultures) and the *Staphylococci*, it was rare to find more than one species of a genus in a single culture of an ear or throat specimen. Consequently the case-prevalence of a genus could be determined with considerable validity by summarization of the case prevalences of the constituent species. This has been

done to eliminate excessive detail in a number of comparative tabulations in this paper.

Table 5 change presents the case-prevalence of genera and species of bacterial flora cultivated from the initial exudate specimens taken from the 130 subjects of this study. The information is summarized in Figure 1. The data are tabulated in reference to the eight Groups or classes of cases previously described (p. 11). It is evident that the flora found in purulent otitis media is highly variable and involves a large number of species and types—41 in this case not including a few genera within which species identification was not attempted. Very few species occur in a significantly large proportion of cases. The exceptions are the following: *Proteus mirabilis* had a case prevalence over 20% in two Groups. *Staphylococcus aureus* was found in highly significant prevalence in five Groups, ranging from 27% to 81%. *Staphylococcus epidermidis* also occurred in significant proportion in five Groups, ranging from 14% to 39%. *Neisseria catarrhalis* was prevalent in significant proportions in two Groups. Of the streptococci, only *S. salivarius* and *S. faecalis* appeared to be significant in otitis flora, but not even these species attained great prevalence in any of the patient Groups. It is clear that in this series of otitis cases no one species of bacteria can be assigned, overall, a predominant etiological role.

There are interesting shifts in prevalence of species and genera, from Group to Group, indicating ecological change in relation to duration of in-

Fig 1 Comparison of flora of ear and pharyngeal cultures in otitis.

fection. This is more evident when case prevalences are summarized within bacterial genera or families. The resultant pattern is evident in Figure 1. The bacterial groups compared in this figure are not taxonomically equivalent. Six are genera (*Pseudomonas*, *Proteus*, *Micrococcus*, *Staphylococcus*, *Streptococcus* and *Corynebacterium*). One is a family (*Achromobacteriaceae*) represented by genera *Achromobacter*, *Flavobacterium* and *Alcaligenes* in our isolates. One is a tribe (*Escherichiae*) represented by genera *Pachera*, *chla*, *Aerobacter*, *klebsiella* and *Paracolobactrum*. To test the validity of using cumulative case prevalences in this comparison, the sum of prevalences of species in each genus or family was compared with the expected number of isolates calculated from the average number of isolations per case (see "Ratio" column for initial cultures, Table 2). The differences between the actual and calculated prevalences were comparatively small. In those instances where the actual cumulative prevalence exceeded the calculated, more than one species of a genus had occurred in a few samples. Where the cumulative prevalence was less than the calculated, a few minor species had not been included in the comparison.

Bearing in mind the duration of otitis in each patient Group (see p. 11) and the detailed case prevalences of species (Table 5), the comparisons of initial cultures illustrated by Figure 1 are patho-ecologically significant. In the cases with duration of 6 months or less (Groups I, II and III), the preponderant flora, by far, were the gram positive cocci (*Staphylococcus* and

were not found in otitis exudate cultures. The distribution of genera and species in the throat and otitis exudate cultures is summarized in Table 7. There was no one species of greater prevalence in the otitis flora of this community of cases which was not also found in the throat flora.

Although in most instances the same genus or family of bacteria was found in both ear exudate and in the throats of persons having otitis, the prevalence in one site was rarely equivalent to the other. Indeed there was often considerable disparity. This can be viewed as being etiologically significant in some comparisons. For instance in Figure 1 note the much greater prevalence of *St. phylogococci* in ear exudate than in throat cultures in Groups I, II, III, VII and VIII as well as the inversion of this disparity in Groups IV and V. In contradistinction, the *Streptococci* were almost consistently less prevalent in ear exudate than they were in throat flora of these patient Groups. These trends in comparative prevalence might be taken to indicate a more pathogenetically significant role and invasive activity for *St. phylogococci* in acute, early chronic and late recurrent otitis than

See p. 11 for definition of Groups.

Streptococcus) In the cases with duration lying between 6 months and 5 years (Groups IV, V and VI) the prevalence of the cocci was greatly reduced and the prevalence of gram negative organisms was greatly increased especially *Proteus*. In cases of extreme duration—between 5 and over 10 years (Groups VII and VIII)—there was a resurgence of *Streptococci* and *Staphylococci* while the gram negatives showed a loss of prevalence in Group VII but considerable resurgence in Group VIII. *Pseudomonas* prevalences did not follow the trends of other gram negative bacteria but mimicked the trends of *Staphylococci* and *Streptococci*. The variance in *Corynebacterial* prevalences by patient groups followed those of *Staphylococcus* and *Streptococcus* except for an earlier resurgence. No distinct pattern is apparent in the graph of *Micrococcus* prevalences. It is also interesting to note a considerably lower ratio of isolations per case in the mid range (Groups IV and V) indicating a trend towards predominance of one bacterial species in the exudate of infection in cases with duration of six months to two years. The general predominance of gram positive organisms in Groups VII and VIII may indicate that these were for the most part, cases of reinfection rather than of persistent otitis.

In 61 out of 130 cases, at the time of initial sampling of otitis exudate and prior to treatment a pharyngeal swab specimen was also taken in order to compare throat and otitis flora. The bacteriological findings from the throat cultures are presented in detail in Table 6 and compared graphically in Figure 1. Comparison shows that most of the genera and species found in otitis flora were also found in throat flora. Out of 17 genera found in exudate flora only four of minor importance (*Flavobacterium*, *Caffkya*, *Sarcina* and *Haemophilus*) were not found in the throat samples. Out of a total of 41 species found in the otitis exudate cultures, 30 were also found in the throat cultures. Only 8 out of 38 species found in the throat cultures

Escherichia Paracolon and *Proteus* are not common normal throat flora of the people studied, (2) that their presence in otitis may be due to external contamination and (3) that their presence in the pharynx of otitis patients may be a retrograde contamination of the pharynx via the Eustachian tube. The latter hypothesis is ecologically intriguing, but would require more bacteriological proof for its substantiation.

To explore the possibility of geographic ecological effects, the prevalence of the various genera and species of bacteria were tabulated with regard to the village of origin of the cases. This was done with the data of both the otitis exudate and pharyngeal swab specimens. At first there appeared to be some ecological variation in distribution of kinds of bacteria from village to village. For instance the case prevalences of *Staphylococci* in exudate cultures were respectively 55.5% 20.7% 29.5% 52.5% 46.5% and 0 in villages 1 through 6. The prevalences of *Proteus* in the same series were respectively 13.0% 24.1% 33.3% 27.9% and 57.1%. To check the validity of these observations the distribution of cases, by chronicity was also tabulated by village. When the case-chronicity distribution was checked against the bacterial genera and species distribution, the geographic factor was eliminated from consideration. In other words, the distribution of genera and species of bacteria in otitis among the villages followed the distribution of cases by chronicity. For example in villages where cases classified in Groups III, IV and V predominated, the prevalence of *Staphylococci* was low and of *Proteus* relatively high. In villages where cases of Groups I, II, III, VII, and VIII predominated, the prevalence of *Staphylococci* was high and of *Proteus* relatively low (consult Figure 1 to see the basis of correlation).

Thus, geographic ecological factors did not appear to be significant in this study. This observation cannot be extrapolated to apply to comparisons between more widely separated geographic areas. The author has, in other studies, gained evidence of significant involvement of geographic discontinuity in the distribution of viral agents and diseases (8, 9 and 10) and of pharyngeal flora (11) among residents of various areas in the American Arctic. Similarly the comparison of otitis flora from areas more widely separated than those reported here may reveal geographic ecological factors.

In the course of successive visits to the study villages, each time the project nurses or physicians examined a person with persistent or recurrent otitis, a swab sample was taken for microbiological evaluations. The overall isolate ratios of these "Following" cultures are shown in Table 2 and the distributions of intervals between first and last cultures are shown in Table 3. The case-prevalences of various species and cumulative case-prevalences of various species and cumulative case-prevalences of species within genera, according to duration of otitis, are summarized in Table 9 and compared in Figure 2. In interpretation of the ecological significance of these data, it must be remembered that all of the "Following" cultures were derived from patients under treatment with antibiotics and sulfonamides. The bac

is characteristic of streptococci. No general patterns are discernible in the ear-throat flora relationships of the other genera and species, however if the number of samples had been larger a significant pattern might have emerged for these species of low prevalence. The overall comparisons (last column) might be interpreted to indicate that the bacterial groups of greater etiological significance, by virtue of greater prevalence in ear exudate over that found in the throat, were the genera *Staphylococcus*, *Proteus*, *Corynebacterium* and family *Achromobacteriaceae* (primarily genus *Alcaligenes*). Undoubtedly the *Streptococcus* group was also highly significant from the etiological standpoint but its prevalence in the throat consistently outstripped its prevalence in otitis exudate.

To check on the normalcy of the throat flora of otitis patients, throat swab samples were taken from 54 children and youths attending a boarding school in a village in the same general geographic area as the demonstration villages. None of these children had otitis at the time of the sampling. The representation of bacterial genera and species in these samples in comparison with the throat flora of patients is summarized in Table 8. For the most part the same genera were represented, the more notable exceptions being the absence of *Escherichia*, *Paracolobactrum* and *Proteus* species in the samples from the normal individuals. In addition the normal throat flora contained fewer species representing those genera which were found in both the otitis cases and the control subjects. These results suggest (1) that

Escherichia Paracolon and *Proteus* are not common normal throat flora of the people studied, (2) that their presence in otitis may be due to external contamination and (3) that their presence in the pharynx of otitis patients may be a retrograde contamination of the pharynx via the Eustachian tube. This is also true of prevalences of *Proteus* species in those cases which persisted over 8 months. Except for the 6 to 8 month group, *Strepto-*

Fig. 2 Comparison of flora component of initial and following cultures.

cocci showed a large increase in prevalence in the otitis cases of longer duration a considerable proportion of this increase was due to *Enterococci*. The case-prevalence of *Corynebacteria* also reached a significantly high level in the cases of greatest duration. *Staphylococcus* prevalence fluctuated but this did not reach significantly greater peak levels than those found in untreated cases. From Table 2 it can be noted that there was a general trend towards a larger number of isolations per sample in the Following cultures. This is corroborated in detail by the isolation ratios. From comparison of the data of Table 5 and of Table 6 and as summarized in Figure 2 it appears that antibiotic therapy may have had a selective effect on the bacterial flora in persistent otitis, and apparently favored the relative increase in prevalence of *Streptococci* particularly *Enterococci*. *Micrococci*, *Staphylococci* and *Corynebacteria* remained significant throughout although their prevalences were subject to considerable fluctuation.

To explore in detail the matter of change in flora composition during treatment, the Following cultures from individuals of Groups I, II and III at 3-4 months and at 12 months were compared with the Initial cultures. These three groups were used for the comparisons because their Initial culture flora were similar in taxonomic character. The following tabulations were made:

- (a) The number of species found in the Initial culture
- (b) The number of species which were present in the Initial culture but not in the Following culture (at 3-4 months and at 12 months) and
- (c) The number of species present in the Following culture which were not present in the Initial culture

The comparison of 3-4 months change in 22 cases showed that 79% of the species found in Initial cultures were absent in the Following cultures. In eight cases in which 12-month comparisons could be made, 88% of the species of the Initial cultures were absent in the Following cultures. At both 3-4 months and 12 months, the Initial species lost were replaced by a larger number of different species. Since we did not have untreated cases to follow—and it would have been unthinkable to establish such a control group—the implications of antibiotic treatment in the taxonomic shift of flora must be judged from the sensitivity data presented later.

As an additional check on the patterns of microbial infection a comparison was made of the flora recovered simultaneously from the left and the right ear of persons with bilateral suppurative otitis. The comparisons were graded as

- (a) Identical flora
- (b) Flora similar for most part
- (c) Flora similar in minor part, and
- (d) Flora entirely different

The results are tabulated in Table 10

These data show that in bilateral otitis, the majority of cases may have flora in one ear which is quite dissimilar taxonomically from the flora of the other

In general these comparative findings indicate that the microbial etiology of suppurative otitis media is not static—that once the pathogenetic chain of events is initiated and the disease is inadequately treated, consecutive changes of flora occur which, for the most part are derived from normal pharyngeal flora and to some extent from environmental contaminants.

TABLE 10 Comparison of flora from cultures of right and left ear in bilateral otitis.

	Initial cultures 22 cases ()	Following cultures 46 cases ()
(a) Identical flora in both ears	9.1	6.5
(b) Flora similar most part	36.3	36.1
(c) Flora similar minor part	22.7	36.1
(d) Flora entirely different	31.8	21.3
Total	99.9	99.9

Fig. 2. Comparison of flora components of initial and following cultures.

coec showed a large increase in prevalence in the otitis cases of longer duration a considerable proportion of this increase was due to *Enterococci*. The case-prevalence of *Corynebacteria* also reached a significantly high level in the cases of greatest duration. *Staphylococcus* prevalence fluctuated, but this did not reach significantly greater peak levels than those found in untreated cases. From Table 2 it can be noted that there was a general trend towards a larger number of isolations per sample in the Following cultures. This is corroborated in detail by the isolation ratios. From comparison of the data of Table 5 and of Table 6 and as summarized in Figure 2 it appears that antibiotic therapy may have had a selective effect on the bacterial flora in persistent otitis, and apparently favored the relative increase in prevalence of *Streptococci* particularly *Enterococci*. *Micrococci*, *Staphylococci* and *Corynebacteria* remained significant throughout although their prevalences were subject to considerable fluctuation.

To explore in detail the matter of change in flora composition during treatment the Following cultures from individuals of Groups I, II and III at 3-4 months and at 12 months were compared with the initial cultures. These three groups were used for the comparisons because their initial culture flora were similar in taxonomic character. The following tabulations were made:

ANTIBIOTIC SENSITIVITY STUDIES

The kind of antibiotic sensitivity test system used was of clinical diagnostic grade. Nevertheless, a high degree of standardization in the conduct and reading of the tests was developed by the microbiological staff. Consequently the test data was satisfactory for purposes of comparison of the sensitivities of flora cultivated from the cases under study.

As interesting as it might be from the microbiological aspect, it is not possible within the scope of this paper to compare the antibiotic sensitivities of individual microbial species from case to case. Since the study had a strong clinical orientation the important question to answer was: Which antibiotic or combination of antibiotics is likely to be efficacious in the treatment of the individual case as it is presented? Further there is no reasonable basis for the designation of any one of several species found in a sample of otitis exudate as the etiological agent. All the flora found are under suspicion. Consequently the antibiotic sensitivities of the composite flora of an otitis case are important to the physician who must determine the agents and regimen of treatment. Since it has been shown in the foregoing that flora changes with duration, it is to be expected that the spectrum of sensitivity also changes with duration. The data have been tabulated to elucidate the changes that did occur. The categories of sensitivity as stated before were: "Resistant," "Slightly Sensitive," "Moderately Sensitive" and "Very Sensitive."

toward 10 antibiotics by case Group in relation to duration of infection (see p 11) is given in Table 11 and presented graphically in Figure 3. These data represent the composite sensitivity of the initial cultures. Since the use of the proprietary medication containing them was introduced late in the study, Neomycin and Polymyxin were not tested as extensively as the other antibiotics, therefore the distribution of sensitivity toward those two agents provide less reliable indices than the data obtained on the others employed in the tests.

The table and graph show that none of the antibiotics tested except possibly for Neomycin, had a high degree of activity against all of the flora encountered in any one Group of cases. Considering the variety of bacterial species involved in the tests, these results are to be expected. The less active were Polymyxin, Penicillin and "Tri Sulfa." Parenthetically it is of interest to point out that Penicillin and "Tri Sulfa" were the agents most often prescribed for initial treatment of the cases encountered in this study. Of all of the antibiotics tested, Neomycin was by far the most active against the bacterial isolates tested against it. Chloromycetin and Terramycin were moderately active against the isolates encountered in most Groups, except for Group VI. Erythromycin and Tetramycin activities reflected to a large extent the distribution of gram positive organisms among the Groups, particularly *Staphylococci*, i.e., these antibiotics scored higher in the Groups having the greater proportions of gram positive microflora. The opposite was found with Streptomycin which scored better in the tests against flora with

the higher proportion of gram negative bacteria. No particular trend was apparent in the distribution of sensitivities to Aureomycin.

The composite antibiotic sensitivities of the flora of the Following cultures from each Group are presented in Table 12 and graphed in Figure 4. Not many trends of sensitivity change are apparent from these data. The flora of most Groups were unmistakably less sensitive to Neomycin and Polymyxin (except in Group VIII). There were, in general, less marked but significant shifts toward decreased sensitivity to most of the antibiotics.

To pursue further the issue of change in antibiotic sensitivity of otitis flora with the shift in taxonomic composition and duration of infection, the antibiotic sensitivities of the flora of cultures involved in the 3-4 months and 12 months comparison (see p. 21) were tabulated. These data are given in Tables 13 A and 13 B.

In the 3-4 month comparison, no general trends in antibiotic sensitivity changes were apparent. The species which were present both in the Initial and the 3-4 month Following cultures showed moderate decreases in sensitivity to Neomycin, Polymyxin, Penicillin, Chloramycetin, a marked decrease in sensitivity to "Tri Sulfa" and a moderate increased sensitivity toward Terramycin, Erythromycin, Tetramycin, Streptomycin and Aureomycin. The new species in the 3-4 month flora of the Following cultures were

slightly or moderately more sensitive to the antibiotics tested except for Terramycin, Erythromycin and Tetramycin where there were slight decreases in sensitivity.

The 12 month comparisons were necessarily based on a small group of cases. Because all of these were cases found early in the study the initial cultures were not tested against Neomycin and Polymyxin and sensitivity comparisons for those antibiotics were not available. With regard to the other antibiotics, the species found both in the initial and 12 month Following cultures were markedly more resistant to all except Streptomycin where there was a decided shift toward greater sensitivity. This reflects the previously described trend towards persistence of gram-negative flora (see Table 9). The "New" flora showed less consistent sensitivity patterns to the antibiotics, varying from marked insensitivity to Penicillin and Tri-Sulfa, to moderate sensitivity to Chloramycetin, Erythromycin and Aureomycin. The data suggest that antibiotic treatment has a selective effect on the flora of chronic otitis in that those species persist which are less sensitive to the commonly used antibiotics.

Since the emergence of antibiotic-resistant strains of *Staphylococcus aureus* has been a matter of epidemiological concern in recent years, the isolates of that species were studied with particular attention to shift in anti-

biotic sensitivity in the course of middle ear infection. Table 14 presents the distribution of grades of sensitivity to nine antibiotics and Tri Sulfas of the *S. aureus* isolates recovered at Initial culture of untreated cases, compared with the sensitivities of isolates recovered from cases with persistent otitis after 4 or more months of treatment. No general trend in nor drastic change of sensitivity was found in comparison of the Initial and Following cultures. The sensitivities of the latter toward Tetramycin, Streptomycin, Aureomycin and Neomycin increased to a moderate degree. Moderate decreases in sensitivity toward Polymyxin, Penicillin and Chloromycetin were found in the case of Tri Sulfas and Terramycin, both greater and less sensitivity categories enlarged at expense of intermediate categories. Certainly these data do not indicate the induction of antibiotic resistant *S. aureus* as a consequence of extended antibiotic therapy.

DISCUSSION

Detailed discussions and interpretations have been given in the foregoing in conjunction with the presentation of data. There remain some important general issues which require discussion to clarify the purpose of this paper and our conclusions.

At onset of our studies we did not presume that we would define the primary etiology of otitis media. We did expect that most of the cases of otitis coming under study would be presented at a stage when the advent of secondary pathogenic agents would have obscured the initial pathogenetic agents and events. Nevertheless, we felt that the microbial aspects of otitis

media, as we encountered them, would be issues of basic pathoecological importance. Furthermore, we felt that such studies could be of considerable practical importance for the stages of otitis media studied in our project are, by far the more common kinds found among the medically-indigent populations of the world, where early uncomplicated otitis media rarely receives prompt and adequate medical attention. In such areas the physician is usually confronted with suppurative otitis, a ruptured tympanic membrane and a bacteriologically-complicated infection.

Since the time of our project, great strides have been taken in the definition of the primary etiology of otitis media. In effect, the excellent work of Berglund, Grönroos and associates (12, 13, 14 and 15) have demonstrated a primary etiological role for the Respiratory Syncytial Viruses (RSV) and have shown coexisting RSV and bacterial infection in acute otitis media. Their later studies indicate that while RSV infections appear to be primary and incitatory it is the coexisting or subsequent bacterial infections that cause the more destructive and persistent pathologic events. They thus have provided scientific proof for a hypothesis long held by those who have studied and treated otitis media.

Those microbiological studies which have utilized otitis media exudate aspirated by needle puncture of the unruptured tympanum have demonstrated a rather simple bacterial flora—usually one species and more frequently a gram-positive coccus. (See Lahtikainen [4] and Grönroos and associates [5].) The cases of perforating purulent otitis in our study presented a greatly complicated bacteriological picture. Contrary to some generally held presumptions, the results of this study indicate that a large proportion of the kinds of flora found in chronic or recurrent exudative otitis is derived from the nasopharynx, rather than external contamination. Further there is some probability that external flora which do become established in otitis may in turn, become established in the pharyngeal flora of the diseased person. The microbiological features of otitis change in time—sometimes so rapidly that the flora of cultures taken a week apart may differ at least in part.

Persistent otitis media, on the basis of our results, appears not to be a chronic, but a recurrent disease of shifting microbial etiology. One may assume certain general probabilities, such as the predominance of gram-positive cocci in the flora during the first few weeks and gradual conversion to a flora dominated by gram negative bacteria thereafter. Nevertheless, in order to provide assiduous medical attention and to select the mode of treatment on a rational basis, it is highly desirable and indeed, essential, that the composition and antibiotic sensitivity of the flora present be determined culturally at successive stages in the clinical management of the case. The field physician in this study found that the bacteriological analyses, including the antibiotic sensitivity determinations, provided invaluable assistance in determining the course of clinical management and hastened the termination of infection in many cases.

The determination of the antibiotic sensitivities of a pure culture of a microorganism cannot be considered as absolute prediction of the efficacies of those antibiotics when used in the treatment of infections caused by the same microorganism. Many other factors in the pathogenesis and course of the disease may modify the effect of antibiotic therapy. Nevertheless, it is generally advisable to select antibiotics for treatment of disease according to the sensitivities of the causative organism. The results of this study indicate that the physician may have to change the antibiotic therapy in accordance with the shift in microbial flora in persistent or recurrent otitis media. It is quite noteworthy that the more commonly used therapeutic agents at the time of this study—sulfonamides and penicillin—were consistently the less active against the microbial flora which we encountered in perforating purulent otitis media. However, our tests did not include a determination of the effectiveness of various concentration levels of antibiotic or sulfonamide. Our comparisons were among components of flora with reference to a standard concentration (medium level). It must also be kept in mind that the microbiological situation of our cases was entirely different from that of early unperforated cases, such as studied by Lähikainen (4) and Grönroos and associates (5).

The ecological effect of antibiotics appeared to be considerable in that resistant flora persisted in a proportion of treated cases. There was no indication, however, that antibiotic therapy led to any substantial absolute increase in resistance of any one component of the flora. These facts again indicate that serial microbiological study of persistent cases should be carried out to determine flora and antibiotic sensitivity shifts.

In general the etiology of otitis media is considered to be ascending infection from the nasopharyngeal tract provoked by upper respiratory disease of viral etiology. We would agree with this concept. In addition, it is probably true that the incidence and severity of this disease among American Indians and Alaskan Eskimos is linked to their medical indigence, general poverty and status of health education. But considerations of etiology and predisposition to otitis media cannot stop with microbiological and socioeconomic factors. The abnormally high prevalence of otitis media among Alaskan Indians and Eskimos, as well as among other Indian groups (16, 17 and 18) may arise, in part, from anatomical characteristics which predispose to ascending infection of the auditory tract from the nasopharynx. A number of workers have drawn correlations between occurrence of otitis and the degree of pneumatization of the temporal bone (see Lähikainen [4]). Another factor may be the relative size, length and direction of traverse of the Eustachian tube and its relation to adenoidal structures. These factors deserve rather rigorous examination among the Indian and Eskimo population, both to elucidate etiological factors and to derive ways of defining that portion of the population with the greater predisposition for otitis media. Hopefully too, current studies on respiratory virus infections which incite otitis may lead to means of immunization to prevent the disease.

SUMMARY AND CONCLUSIONS

The bacteriological study of 130 cases of purulent, perforating otitis media among Eskimo and Indian children in Westward Alaska indicates the following

1. By their presence in otitis exudate, more than 40 species, belonging to 18 genera are linked to the etiology of bacterial otitis media. The major proportion of these species are commonly found in the pharyngeal flora of the human population studied. A minor proportion appear to be derived from external contamination.

2. Once otorrhea has been established, the microbial species associated with suppuration are usually heterogeneous, multiple and changing.

3. Since the composition of microbial flora is not static in persistent or recurrent otitis, microbiological studies with antibiotic sensitivity determinations should be repeated at intervals to allow adjustment of antibiotic therapy.

4. Geographic factors did not appear to have microbiological ecologic implication in this disease in the area and population studied.

5. Antibiotic therapy appeared to affect the microbiology of persistent otitis in that the more resistant bacteria were found to persist, but the induction of antibiotic resistance was not perceived.

6. The bacteriological facts alone do not fully explain the extremely high prevalence of this disabling disease among Alaskan natives. The eventual control will depend upon studied improvement of medical care and, possibly immuno-prophylaxis of incitatory viral infections.

ACKNOWLEDGMENT

This work was facilitated by the excellent services and whole-hearted cooperation of public health nurses Lorraine D. Singer, Edna Backen, and Mary E. Coonrod, health educator Elizabeth E. Mumm, and by Mrs. L. G. Oswald, laboratory assistant. The logistic support of the Childrens Bureau, U.S. Dept. of Health Education and Welfare and of the Division of Health, Alaska Dept. of Health and Welfare is acknowledged gratefully.

INTRODUCTION

The taste receptors in man and the higher animals are chiefly situated in special groups of cells, namely taste buds, which are located on the tongue and in the pharynx. A knowledge of the normal structure of the taste buds is of importance for the understanding of the physiology of taste and there is a comprehensive literature about these structures (Lovén 1867, Schwalbe, 1868, Hermann, 1884, 1888, Ranvier 1888, Retzius, 1892, von Lenhossek, 1893/04, Gräberg, 1899, Kolmer 1910, Heidenhain, 1914, Olmsted, 1920 b). Many of these studies have been made with old-fashioned techniques and the illustrations are very often imperfect. By means of technical improvements in, amongst other things, microphotography and microscopy the possibilities of analyzing and reproducing structural details, have been improved fundamentally. During the last decade a number of publications have appeared which contain illustrations that were made with the aid of electron microscopy (Engström and Rytman 1956 a, b, Trujillo-Cenóz, 1957, de Lorenzo, 1958, 1960, 1963 a, Murray and Murray 1960, 1967, Nemetschek-Ganler and Ferner 1964, Farbman, 1965 a, Gray and Watkins, 1965). In spite of these studies there is still an imperfect knowledge concerning the normal structure of the taste buds. Our knowledge of the innervation of the taste buds is also rather deficient. We are unsure of the changes appearing after injuries to the nerves belonging to them. Another still unsolved problem concerns the ability ascribed to taste buds to regenerate after transection of the taste nerves.

These problems have received increased interest in connection with the development of modern oto-surgery. Every day all over the world a great number of microsurgical operations in the middle ear are being carried out. At these operations the chorda tympani, the taste nerve in the anterior part of the tongue in its intratympanic course is exposed to injury or even transected. As a result of these injuries to the chorda tympani during the operation in the middle ear disturbances arise in the taste function of those parts of the tongue which are innervated by this nerve. It is therefore very common for patients to report discomfort from the tongue after a middle ear operation.

A. CLINICAL PART

I. SURVEY OF THE LITERATURE

The course of the chorda tympani in the middle ear and its function

The chorda tympani leaves the facial nerve proximally to the stylomastoid foramen and enters the middle ear through the posterior canaliculus together with the posterior tympanic artery. It runs between incus and malleus and passes above the insertion of the tendon of the tensor tympani muscle on the malleus to the anterior canaliculus in the petrotympanic fissure, where it leaves the middle ear. The intratympanic course varies. In certain cases it runs vertically and is then partly hidden by the posterior margin of the tympanic sulcus. In other cases, however, the chorda tympani has a more horizontal direction.

The chorda tympani carries afferent taste fibers from the anterior two thirds of the tongue but also contains efferent secretory fibers for the submandibular and sublingual glands. It is also questioned, whether the chorda tympani contains secretory fibers for the parotid gland (Reichert and Poth, 1923; Yannakis and Mannoldis, 1938; Rauch, 1959; Diamant and Wiberg, 1965). The nerve is attributed a motor function with innervation of the levator veli palatini muscle (Moritz, 1936; Nickl, 1950). This function, however, is denied by Zöllner (1942) and Tiedemann (1965). The chorda tympani is also considered to contain fibers of touch, pain and temperature for the anterior two thirds of the tongue (Costen et al., 1951; Tiedemann, 1965).

The taste function after operation for otosclerosis

A great number of authors discuss the frequency and effect of chorda tympani lesions in surgery for otosclerosis. It has been clearly shown experimentally (Ho, 1937; Costen et al., 1951; Eliasson and Gisselsson, 1954; Frenchner and Preber, 1954) and clinically (Krarup, 1958 b; Rice, 1963; Bull, 1965; Herrmann, 1965; Roseburg, 1966; Gerhardt and Berndt, 1967; Wiberg, 1969) that excision of the chorda tympani gives a total disappearance of the taste sense within the innervation area. The patient's subjective experience of the loss of taste, on the contrary, varies with time after the operation and perhaps also with the result of the operation. Gerhardt and Berndt (1967) among others have pointed out, that the patient's experience of the improvement of hearing is so dominating that the taste loss is completely suppressed.

Besides the loss of taste the patients not infrequently notice a feeling of dryness in the mouth which often remains. Many items of food also are perceived to have a different taste.

The fact that the patient's discomfort is, after a time, relatively insignificant, has in all probability contributed to the fact that the experimental investigations are so few. Human experiments with biopsies from the papillae of the tongue after injury to the chorda tympani have not been performed. It is known that a lesion of the chorda tympani causes reduced or abolished taste function within the innervation area. But, whether any form of regeneration comes about, is not shown in the literature.

The above discussed problems are of great clinical interest especially since patients with bilateral otosclerosis frequently undergo operations on both sides. They thereby run the risk of getting impairments of the taste on the anterior two thirds of the tongue.

In experiments on animals some authors have shown regeneration of the taste buds after suture of the taste nerves (Boeke, 1917. Olmsted and Pinger 1936. Aroy and Monzingo 1942. Guth 1958). But there is no evidence in the literature that anyone has carried out suture of the chorda tympani on human beings after operative injuries.

With the clinical results and the experimental animal investigations as background it is necessary to discuss the possibilities of restoring the continuity in the injured chorda tympani. Reinnervation and regeneration of the taste buds could then be induced and the function of taste would be improved.

The aim of the present investigation is to study the normal structure of the taste buds and to investigate problems of importance for the understanding of the effect of injuries to taste nerves. This study has been carried out along the following lines:

I Clinical investigation

A) To study the taste function in patients operated upon for otosclerosis by using different tests.

II Experimental investigation

A) To study the normal structure of the taste buds in rabbits, by using light, phase contrast and electron microscopy.

B) To study after nerve transection and nerve suture, the morphological changes of taste buds in rabbits.

III Discussion of methods of repairing the injured chorda tympani

* more than 6 months.

In most investigations only the subjective taste disturbances postoperatively are registered after division respectively preservation of the chorda tympani. Table 1 is a literature review of published follow up series in cases with divided chorda tympani. Bull (1905), Gerhardt and Berndt (1907) and Wiberg (1909) are the only ones, who have performed objective tests with solutions alone or combined with electrical tests. The frequency of persistent subjective taste disturbances varies considerably between 2 % and 34 %. The number of cases without subjective taste disturbances varies between 20 % and 77 % average 36 % (Kersley and Gray's material excluded). These authors point out that the number of patients with subjective impairments is higher if they question them than if they put the spontaneous reports together. In the table Roseburg's results are founded on spontaneously reported impairments which explains the high percentage of unimpaired taste.

Even if the chorda tympani is not divided at the operation but is only stretched or suffers other trauma disturbances in the function of taste may arise and the patients' subjective experiences can be both pronounced and protracted (Table 2). The number of cases without subjective taste disturbances varies between 52 % and 94 % average 75 %.

The majority of surgeons consider that the chorda tympani if possible should be preserved. There are however as seen from table 3 surgeons, who as a routine or in a high percentage of cases divide the chorda tympani believing that injury to the chorda tympani through stretching or partial rupture causes more pronounced postoperative impairment and a higher percentage of permanent loss symptoms (Compare table 1 and 2).

Bilateral surgery for otosclerosis is today carried out more often than in the past. This means that the chorda tympani may be injured or divided bilaterally. Bull (1905) reports 32 patients with bilateral division of the chorda tympani. 25 patients (78 %) have persistent symptoms. Besides a loss of taste a metallic taste and an aversion to certain items of food the patients have a feeling of dryness in the mouth.

Clinical test methods for taste

Taste like smell has peripheral receptors belonging to the group of chemical sense organs. The adequate stimulation for taste is molecules and ions in solutions.

The taste impression can be classified within the following qualities: sweet, salty, sour and bitter. It is not possible to give any relation between the chemical constitution of a substance and its taste (Pfaffmann 1959).

The oldest and still the most applicable clinical test for the sense of taste is the use of solutions of varying kinds with a trial-and-error method. This method is qualitative but by varying the concentration of the solution it is possible to get a semi-quantitative estimation (Bornstein 1940 b).

Table 1 Survey of literature Frequency and duration of postoperative taste impairment with divided chorda tympani

) more than 6 months.

The sense of taste can also be stimulated in a galvanic way. Sulzer (1752) and Volta (1792) have observed that a taste sensation arises in galvanic stimulation of the tongue. It is however only during the last decade that methods have been worked out and apparatus constructed which are suitable for clinical use in electrical taste testing. Krarup (1958 a) has constructed an apparatus, the so-called electrogustometer for testing the taste function. His results after the clinical application are reported in 1965. In later years a number of studies have been published on electrical taste investigations, in which Krarup's basic principles have been used (Feldmann and Maier 1959; Herbert et al., 1962; Tomila and Pascher 1964; Pulic et al., 1964; Bull 1965; Föns and Osterhammel 1968).

In stimulating the sense of taste in a galvanic way a sour to metallic taste is created at the anode and an alkaline sensation is created at the cathode.

Comments. The chorda tympani contains gustatory nerve fibers to the anterior two thirds of the tongue. The nerve can be injured at surgery for otosclerosis but also in connection with other operations in the middle ear for hearing improvement or for cleaning. Fractures of the temporal bone and facial nerve palsy sometimes cause damage to the chorda tympani. The clinical investigations about taste function after surgery for otosclerosis show that both when the chorda tympani is preserved and when it is divided the patients perceive taste disturbances. In most studies the taste is only subjectively examined. The results vary and are dependent upon the following factors: the way in which the patients are questioned, if they are informed and tested preoperatively and if they perceive hearing improvement. It is thus difficult to compare the results in the different studies. To get conclusive results it seems necessary to perform not only subjective but also objective taste examinations.

Table 3 Survey of literature. Frequency of divided chorda tympani at surgery for otosclerosis

Author and year	Number of cases	Number with divided chorda tympani
Cusford 1961	414	248 (60%)

Gerhardt and Berndt, 1967	315	39 (12%)

II MATERIAL

During the years 1963 to 1967 in the Department of Otolaryngology Sahlgrenska sjukhuset, in Göteborg, 861 operations for otosclerosis have been performed. The operations have been done by different surgeons belonging to the staff of the clinic. With a few exceptions stapedectomy according to Schuknecht has been performed. The chorda tympani has been divided in 70 patients or about 10 %.

For the present investigation a randomized material of 141 patients has been used and divided in two groups:

I. Patients examined preoperatively and 1 week following the operation and then 1, 6 and 12 months postoperatively. This group comprises 74 patients. The chorda tympani was divided in 12 and preserved in 62 patients.

II. Patients operated upon unilaterally and examined once > 12 months postoperatively. This group comprises 67 patients. The chorda tympani was divided in 22 and preserved in 45 patients.

The ages ranged from 18 to 73 years with a mean of 47 years. All patients have been operated upon with local anaesthesia and by a transmental approach. In almost every case it has been necessary to drill away bone from the posterior margin of the tympanic sulcus. The approach to the middle ear and especially to the stapes plate is often obstructed by the chorda tympani. At the operation the chorda tympani can be divided or preserved. Preserved chorda tympani includes cases where the continuity of the nerve at the operation had been preserved. This group, however, comprises cases where the nerve had not been touched at all, stretched, displaced or maltreated in another way.

III METHODS

Subjective taste examination

The patients have been questioned about alterations in the taste of foods, difficulties in differentiating various liquids, especially tea and coffee, and the occurrence of a metallic sensation on the tongue. The patients have also been questioned about pain and numbness of the tongue and dryness of the mouth. In the present investigation changes in this respect have been defined as impaired taste.

Electrical taste examination

Krarup's electrogustometer has been used in accordance with the technique applied by him. In this apparatus the stimulus intensity ranges from 0-370 μ A. The intensity is recorded on a scale logarithmically divided into 23 steps. Every step corresponds to 1 Electric Gust Unit (EGU).

Normally there is a great individual variation of the threshold for the electrical stimulus. Krarup however considers a stimulus of 23 EGU as the limit for total loss of taste. A difference in the threshold of at least 7 EGU should be regarded as significant. As controls only the preoperative threshold value or that of the unoperated side of the tongue were used.

The anode the different electrode was applied to the tongue and the cathode the indifferent electrode was applied to the wrist resting on a moistened compress. The patient was informed about the principles of the method and the procedure of testing. The tongue was held softly stretched forward and the anode, a stainless steel disc with a diameter of 5 mm was applied with a light pressure to the tongue. 2 regions were tested: first the border of the tongue $1\frac{1}{2}$ cm from the tip, second 2 cm dorsal and $1\frac{1}{2}$ cm lateral from the tip of the tongue. The threshold value for the stimulation was determined with 3 measurements by varying the strength of the stimulus around the primary value. Both halves of the tongue have been tested and compared with each other. To avoid adaptation it was of importance that each stimulation did not last for more than 2 seconds and was not repeated within 30 seconds. In the present investigation the post operative taste sensation has been defined as impaired when the taste threshold has increased more than 3 EGU compared to control value.

Taste examination with solutions

In testing with taste solutions, Börnstén's (1940 b) method has been applied with the following solutions and concentrations.

Solutions	Concentration in percentage		
Sucrose	4	10	40
Sodium chloride	2.5	7.5	15
Citric acid	1	5	10
Quinine hydrochloride	0.075	0.5	1

The patient was asked to put out the tongue and lean the head so that the test area was kept in a horizontal position. 1 drop of the test solution was applied to the front of the tongue by a pipette. It was of importance that the solution did not run backward on the tongue or down in the bottom of the mouth. The patient was urged not to draw in the tongue before the taste sensation had been pointed out on a table indicated with the different taste qualities and water. The stimulation time varied between 10 and 15 seconds. Both the anterior halves of the tongue have been tested after each other and with increasing concentrations of the solutions. The idea of the significance of impaired taste varies in different investigations. As in the electrical taste test great individual variations of the threshold values exist for the different taste solutions. In the present investigation impaired taste has been defined as increased taste threshold of at least 1 concentration step in at least 2 qualities.

IV RESULTS

The results of the investigations with regard to the percentage of postoperatively impaired taste in the different groups at the various test occasions is registered in table 4.

Table 4 Postoperatively impaired taste function in percentage.

total loss of taste

Preserved chorda tympani

The subjective taste sensation of the patients in group I i.e. patients tested pre- and postoperatively was at the examination of 1 week postoperatively impaired in 50 % of the cases. With time the frequency of taste impairment decreased. At the examination 1 year after the operation 16 % of the patients had impaired taste. In group II where the patient was tested more than 1 year after surgery only 2 % had impaired taste sensation.

By the electrical test the patients in group I showed at the examination 1 week postoperatively impaired taste in 89 % of the patients. As at the subjective taste examination the percentage with taste impairment decreased with time. But at the examination 1 year postoperatively as many as 65 % had impaired taste function. In the follow-up study for more than 1 year in group II about the same percentage (31 %) of the patients had impaired taste.

The results at the examination using solutions was largely in agreement with those obtained for the electrical test, but generally the numbers with taste impairment were lower. In group I 84 % of the patients showed impair

Normally there is a great individual variation of the threshold for the electrical stimulus Kararup however considers a stimulus of 23 EGU as the limit for total loss of taste. A difference in the threshold of at least 3 EGU should be regarded as significant. As controls only the preoperative threshold value or that of the unoperated side of the tongue were used.

The anode the different electrode was applied to the tongue and the cathode the indifferent electrode was applied to the wrist resting on a moistened compress. The patient was informed about the principles of the method and the procedure of testing. The tongue was held softly stretched forward and the anode, a stainless steel disc with a diameter of 5 mm was applied with a light pressure to the tongue. 2 regions were tested first the border of the tongue $1\frac{1}{2}$ cm from the tip second 2 cm dorsal and $1\frac{1}{2}$ cm lateral from the tip of the tongue. The threshold value for the stimulation was determined with 3 measurements by varying the strength of the stimulus around the primary value. Both halves of the tongue have been tested and compared with each other. To avoid adaptation it was of importance that each stimulation did not last for more than 2 seconds and was not repeated within 30 seconds. In the present investigation the post operative taste sensation has been defined as impaired when the taste threshold has increased more than 3 EGU compared to control value.

Taste examination with solutions

In testing with taste solutions, Börnstein's (1940 b) method has been applied with the following solutions and concentrations.

Solutions	Concentration in percentage		
Sucrose	4	10	40
Sodium chloride	2.5	7.5	15
Citric acid	1	5	10
Quinine hydrochloride	0.075	0.5	1

The patient was asked to put out the tongue and lean the head so that the test area was kept in a horizontal position. 1 drop of the test solution was applied to the front of the tongue by a pipette. It was of importance that the solution did not run backward on the tongue or down in the bottom of the mouth. The patient was urged not to draw in the tongue before the taste sensation had been pointed out on a table indicated with the different taste qualities and water. The stimulation time varied between 10 and 15 seconds. Both the anterior halves of the tongue have been tested after each other and with increasing concentrations of the solutions. The idea of the significance of impaired taste varies in different investigations. As in the electrical taste test great individual variations of the threshold values exist for the different taste solutions. In the present investigation impaired taste has been defined as increased taste threshold of at least 1 concentration step in at least 2 qualities.

IV RESULTS

The results of the investigations with regard to the percentage of postoperatively impaired taste in the different groups at the various test occasions is registered in table 4.

total loss of taste

Preserved chorda tympani

The subjective taste sensation of the patients in group I, i.e. patients tested pre and postoperatively was at the examination of 1 week postoperatively impaired in 50 % of the cases. With time the frequency of taste impairment decreased. At the examination 1 year after the operation 16 % of the patients had impaired taste. In group II where the patient was tested more than 1 year after surgery only 2 % had impaired taste sensation.

By the electrical test the patients in group I showed at the examination 1 week postoperatively impaired taste in 89 % of the patients. As at the subjective taste examination the percentages with taste impairment decreased with time. But at the examination 1 year postoperatively as many as 55 % had impaired taste function. In the follow-up study for more than 1 year in group II about the same percentage (51 %) of the patients had impaired taste.

The results at the examination using solutions was largely in agreement with those obtained for the electrical test, but generally the numbers with taste impairment were lower. In group I 84 % of the patients showed impaired

ment of taste at the examination of 1 week and 40 % at the examination 1 year postoperatively. At the examination of patients belonging to group II impaired taste was found in 33 %.

Looking upon the patients with preserved chorda tympani from the quantitative point of view not less than 13 % showed total loss of taste as registered by the electrical test as well as testing with solutions.

Divided chorda tympani

The subjective taste sensation of patients with divided chorda tympani was at the examination of 1 week postoperatively impaired in 83 %. The frequency decreased with time. Examination of the same patients 1 year postoperatively showed that only 17 % had impaired taste. The patients belonging to group II had impaired taste sensation in 11 % of the cases.

From 1 week postoperatively and later all patients with divided chorda tympani had total loss of taste both by electrical test and by testing with solutions.

V DISCUSSION AND CONCLUSIONS

In earlier investigations the subjective impairment of taste after surgery for otosclerosis is generally the only parameter used. It is clear that this introduces considerable errors. Many factors are of importance. The percentage of taste impairment is higher if the patients are questioned than if they report spontaneously (Roseburg 1966). The percentage also increases if the patients are informed and tested preoperatively. Further the intellectual status of the patient, the profession, the postoperative hearing gain and several other factors may influence the result. These are all in accordance with the big variations between the results of the earlier investigations based on subjective evaluation of postoperative taste sensation.

To get reliable results it is necessary to perform in addition to the subjective tests, also objective taste tests. In the present investigation electrical tests and testing with solutions have been used. However, it must be stressed that the psychophysical nature of the tests introduces errors. In testing with solutions several other factors may influence the result. The size of the drop varies as does the size of the area on which the drop spreads. These errors are avoided when using electrical stimulation because the size of the electrode standardizes the stimulated area. According to Hrarup (1965) only taste fibers are stimulated at these extremely low currents. Pfaffmann (1941) states that impulses induced by electrical stimulation run in the same fibers as those induced by solutions. Stimulation of regions without taste buds gives no sensation of taste. As strict electro-

physiological methods cannot be applied on man, the electrical test designed by Krarup must be considered as the most reliable taste test today.

In many cases the question concerning the chorda tympani in stapes surgery arises whether it is better to divide than stretch, displace or maltreat this structure. It has been pointed out in the literature that the preservation of the chorda tympani gives a higher percentage of subjective taste impairment than if the chorda tympani is divided. The results in group II (i.e. patients analyzed more than 12 months after surgery) do not speak in favor of this opinion as 9 % had subjective impairment if the chorda tympani was divided at operation but only 2 % if the chorda tympani was preserved.

Compared to other reports, presently there is a strong tendency to preserve the chorda tympani as it has been divided in only 10 % of all operations. It is interesting to see that in patients with preserved chorda tympani, not less than about 50 % had taste impairment as judged by objective testing 12 months postoperatively. This means that even if we try to preserve the chorda tympani definite lesions arise in half of the patients. However these lesions are graded and depending on the big individual variations the taste loss can only be expressed as the difference between the preoperative and postoperative taste threshold. As the limit of total loss of taste is put at 22 EGU according to Krarup it is difficult to evaluate the results. An individual having a high preoperative threshold falls after a taste loss of a few units in the group of total loss while another individual with a low preoperative threshold having a taste loss of many units and thus a greater taste impairment is still judged as having taste. The high percentage of taste impairment (about 50 % by electrical taste test) in this material speaks in favor of the opinion that preservation of the chorda tympani when it obstructs the middle ear and especially the stapes region does not prevent taste disturbances. However the chorda tympani does not only carry taste fibers, but also secretory fibers to the sublingual and submandibular glands and according to some authors (Reichert and Poth, 1933; Lannuilli and Manolidis, 1938; Ranch, 1939; Diamant and Wilberg, 1965) also to the parotid gland. As long as only unilateral surgery for otosclerosis is performed no paramount problems arise. However today bilateral surgery is usual. Good reasons exist to be more acutely aware of the problem of the chorda tympani in connection with surgery for otosclerosis.

B EXPERIMENTAL PART

I SURVEY OF THE LITERATURE

a. The taste organ under normal conditions

The taste receptors in man and higher animals, as previously stated are situated in special cell groups taste buds, which are to be found on the tongue and in the pharynx. On the tongue the taste buds are arranged in papillae of varying appearance and it is possible to distinguish 3 different forms of papillae containing taste buds, namely the fungiform papillae the foliate papillae and the circumvallate papillae. In addition there are the filiform papillae which do not have taste buds.

Patton (1930) Dastur (1961) and Oakley (1967) have discussed the possibility that stimulation of so-called free nerve endings may give gustatory sensation.

Embryology

The first anlage of the tongue appears in the human embryo at a length of 5 mm, as a small bulge in the mucous membrane at the bottom of the primary mouth bend. The tongue muscles are of mesodermal origin and derive from the first, second, third and fourth branchial arches and mainly from occipital myotomes. Every branchial arch has its own nerve and because the tongue develops from a number of origins, its innervation will be complicated. The trigeminal nerve from which the lingual nerve comes belongs to the first branchial arch. The facial nerve with chorda tympani goes to the second branchial arch. The glossopharyngeal nerve is the third branchial arch's nerve while the vagus nerve belongs to the fourth branchial arch (Clara 1949; Hamilton et al., 1949; Langman 1963).

The epithelium of the tongue derives from the same branchial arch as the muscles. At the beginning it is cubical but later differentiates to a stratified squamous epithelium at the same time as presumptive taste buds and papillae appear. The circumvallate and fungiform papillae develop first and are observed in embryos of 20 to 30 mm length. Somewhat later come the foliate papillae. The filiform papillae which lack taste buds, begin to develop in the embryo of 45 mm length (Hellman 1921; Clara 1949; Hamilton et al 1949; Langman 1963).

The age when the taste buds begin to develop during the embryonic stage has been investigated by a number of authors and it is reported to vary between 2 and 7 months (Lustig, 1881; Hellman, 1921). Bradley and Stern (1967) report that the tongue epithelium from an embryo of 7 to 8 weeks has collections of cells with a taste bud appearance but "at 11 weeks the presumptive bud is formed".

It is generally considered that the taste buds are formed from the epithelial basal cell layer in connection with fibers belonging to the taste nerves. When these nerve fibers reach the basal cell layer a differentiating process of the cells takes place. The cells elongate and form groups which resemble taste buds. Depending on how the development proceeds, these cell groups soon have the appearance of definite taste buds with pores (Hermann, 1884; Griffini, 1887; Tuckerman, 1888/89; Gräberg, 1898; Marchand, 1902; Schumacher, 1927; Torrey, 1940; Clara, 1949; Hamilton et al., 1949; Kubota and Kubota, 1960, 1963; Langman, 1963; Farbman, 1963 b; Bradley and Stern, 1967). Hellman (1921) also considers that the taste buds are induced by nerve stimulation, but that the primary taste bud-like formations, called by Hellman *primitive Geschmackszwiebeln*, do not develop into definite taste buds but are reformed. Objections have been raised against the opinion that the taste nerves stimulate the formation of taste buds. It is stated, that all epithelial tissue elements have an inborn capacity to proliferate and differentiate in various organs without the influence of nervous components. According to this later theory papillae and taste buds form first and the growth of nerve fibers should be a secondary process (Herbst, 1901; Harrison, 1904; Patzelt, 1924; McLoughlin, 1961).

The development of taste buds has also been studied by electron microscope. In 1963 Farbman published an electron microscopical study on the development of taste buds on the fungiform papillae in rats and there he describes how the first beginnings of papillae appear as small epithelial bulges, when the embryo is 16 days old. On the 18th to the 21st day prenatally the nerve fibers begin to invade the epithelium and those cells, which are placed nearest the nerve structures contain a rich supply of vesicles. Farbman reports these findings in the following way: "These vesicles have been interpreted as morphological evidence of an interaction between epithelial and nerve processes, an interaction which precedes differentiation of the cells into taste bud cells". At the age of 12 days the taste buds are fully developed and contain the different cell types and the taste pores.

At birth, in human beings, the taste buds are considered to be fully developed and occur in greater numbers than during later life (see p. 18).

Anatomy of the taste organ

The fungiform papillae have a clublike appearance and are seen with the naked eye. Most often they have a more marked red color than the surrounding structures since the keratinizing epithelium is thinner. The stroma in

I SURVEY OF THE LITERATURE

a. The taste organ under normal conditions

The taste receptors in man and higher animals, as previously stated are situated in special cell groups taste buds which are to be found on the tongue and in the pharynx. On the tongue, the taste buds are arranged in papillae of varying appearance and it is possible to distinguish 3 different forms of papillae containing taste buds, namely the fungiform papillae the foliate papillae and the circumvallate papillae. In addition there are the filiform papillae which do not have taste buds.

Patton (1950) Dastur (1961) and Oakley (1967) have discussed the possibility that stimulation of so-called free nerve endings may give gustatory sensation.

Embryology

The first anlage of the tongue appears in the human embryo at a length of 5 mm, as a small bulge in the mucous membrane at the bottom of the primary mouth bend. The tongue muscles are of mesodermal origin and derive from the first, second, third and fourth branchial arches and mainly from occipital myotomes. Every branchial arch has its own nerve and because the tongue develops from a number of origins, its innervation will be complicated. The trigeminal nerve from which the lingual nerve comes, belongs to the first branchial arch. The facial nerve with chorda tympani goes to the second branchial arch. The glossopharyngeal nerve is the third branchial arch's nerve, while the vagus nerve belongs to the fourth branchial arch (Clara 1940; Hamilton et al. 1940; Langman 1963).

The epithelium of the tongue derives from the same branchial arch as the muscles. At the beginning it is cubical but later differentiates to a stratified squamous epithelium at the same time as presumptive taste buds and papillae appear. The circumvallate and fungiform papillae develop first and are observed in embryos of 20 to 30 mm length. Somewhat later come the foliate papillae. The filiform papillae which lack taste buds, begin to develop in the embryo of 45 mm length (Hellman 1921; Clara 1940; Hamilton et al., 1940; Langman 1963).

advancing age there is steady reduction of the number of papillae and also of taste buds. The fungiform papillae occur over the greater portion of the tongue anterior two thirds during the latter part of fetal life or the earliest months of life. They are later greatly reduced in numbers.

No quantitative estimations of the number of taste buds situated on the fungiform papillae are available (Hoffmann 1875 Stahr 1902 von Skramlik, 1925 Schumacher 1927).

It is mainly the circumvallate papillae that have been the object of study first because they are easy to find on the tongue and secondly because they are few in number. In the adult, as earlier stated, taste buds occur on the lateral sides of the papillae and the inside of the wall while in the newborn taste buds have been described also on the top of the papillae. The taste buds on the top, atrophy or disappear as a result of the continual wear of the tongue against the palate when sucking, swallowing and crying. Individual variations with regard to the number of papillae, their size and shape cause great difficulties when estimating the number of taste buds during different periods of life. Von Wyras (1870) calculated the number per papilla at 400, Arnau (1876) at 2500 and Gräberg (1899) at 100 to 150.

Through Heiderich's (1906) and Argy's et al. (1935) investigations it has become evident that the taste buds are passing a progressive involution. Heiderich (1906) could, by serial sectioning of the circumvallate papillae from individuals between 0 and 20 years of age, estimate the number of taste buds to an average of 248 per papilla. This figure is remarkably constant for all ages. In the work of Argy et al. (1935) papillae were also serially sectioned with the following result: in the age group 20 to 70 years there is an average of 208 taste buds per papilla but in the extreme age group 74 to 84 years there are only 88 taste buds per papilla.

Physiological behaviour

Several earlier authors (Ranvier 1888 Hermann, 1888 von Lenhossék 1893/94 von Ebner 1897) have, in their investigations of the structure of the taste buds, observed the occurrence of a varying number of leucocytes within the taste buds. This observation led to the thought that a steady degeneration of cells in the taste buds is taking place. However this degeneration is partly compensated for by simultaneous renewal.

Further support for this hypothesis has been obtained through Hermann's (1888) discovery of mitoses in the lower part of the taste buds. Kolmer (1910) Reizius (1912) and Heidenhain (1914) also supposed that a continuous transformation is taking place in the cells of the taste buds.

It is, however, through the studies of Beldler et al. (1900) Beldler (1903) 1903) Beldler and Smallman (1905) and Robbins (1907) on animals definitely proved that the cells in the taste buds pass a continuous process of degeneration and renewal. Beldler et al. injected colchicine a mitosis inhibitory substance intraperitoneally into rats and then killed the animals and

the papillae consists of connective tissue nerves and blood vessels. In many places the stroma projects into the epithelial layer whereby secondary papillae are formed. The number of papillae vary individually and also with age. As a rule the younger an individual is the greater is the number of papillae. They are scattered over the anterior two thirds of the tongue but are especially numerous near the tip and the anterior margin of the tongue. The number of taste buds in the papillae varies between 5 and 12 (Parker 1922 Bloom and Fawcett 1968). Fungiform like papillae which do not contain any taste buds have also been described (Schumacher 1927 Maximow and Bloom 1952).

The foliate papillae in man are rudimentary while those of some animals, such as rabbit and rat are well developed (Hellman 1921 Schumacher 1927). In mammals the foliate papillae are situated on the lateral sides of the tongue at the border between *radix* and *corpus linguae* and form 4 to 8 parallel ridges with furrows between.

The taste buds occur on the lateral sides of the ridges, but there also are ridges which have no taste buds and this has been considered to be a sign that the papillae are in a state of regressive development. The stroma in these papillae is formed by connective tissue, rich in fat and lymphoid structures (Stahr 1902). The secondary papillae of the foliate papillae are often particularly regular and well developed. In the peripheral areas, the furrows are as a rule more shallow.

The circumvallate papillae 3 to 12 in number are located directly in front of the terminal sulcus and are arranged in a V like formation. The size of the papillae can vary but externally they have the same characteristics and are composed of a central papilla separated by a furrow from the surrounding wall. The taste buds are situated partly on the lateral side of the papilla partly on the inside of the wall facing the furrow (Schumacher 1927 Maximow and Bloom 1952 Bloom and Fawcett 1968). In newborns sometimes there are taste buds on top of the papillae (Hoffmann 1875 Tuckerman 1888/90 Gräberg 1898 Jurisch 1922 Schumacher 1927).

Solitary or smaller groups of taste buds can be found embedded in the epithelium on various places in the oral cavity or the pharynx. Thus, Hoffmann (1875) and Parker (1922) found taste buds on the soft palate above the uvula. In spite of serial sections however von Ebner (1897) Patzelt (1924) and Cairns (1955) could not find any taste bud like structures in this area.

Ponzo (1906) Patzelt (1924) and Märk (1940) have found taste buds on the posterior wall of the pharynx on the glossopalatine arch and on the epiglottis.

In the fetus Patzelt (1924) has found taste buds in the orifice to the esophagus. Schinkele (1942) and Burki (1953/54) have described taste bud like structures in the middle part of the esophagus.

Taste buds seem in general to be fully developed at birth and with

advancing age there is steady reduction of the number of papillae and also of taste buds. The fungiform papillae occur over the greater portion of the tongue's anterior two thirds during the latter part of fetal life or the earliest months of life. They are later greatly reduced in numbers.

No quantitative estimations of the number of taste buds situated on the fungiform papillae are available (Hoffmann, 1875; Stahr 1902; von Skramlik, 1925; Schumacher 1927).

It is mainly the circumvallate papillae that have been the object of study first because they are easy to find on the tongue, and secondly because they are few in number. In the adult, as earlier stated, taste buds occur on the lateral sides of the papillae and the inside of the wall while in the newborn taste buds have been described also on the top of the papillae. The taste buds on the top, atrophy or disappear as a result of the continual wear of the tongue against the palate when sucking, swallowing and crying. Individual variations with regard to the number of papillae, their size and shape cause great difficulties when estimating the number of taste buds during different periods of life. Von Viss (1870) calculated the number per papilla at 400 Krause (1878) at 2500 and Gräberg (1898) at 100 to 150.

Through Heiderich's (1906) and Argy's et al. (1935) investigations, it has become evident that the taste buds are passing a progressive involution. Heiderich (1906) could, by serial sectioning of the circumvallate papillae from individuals between 0 and 20 years of age, estimate the number of taste buds to an average of 248 per papilla. This figure is remarkably constant for all ages. In the work of Argy et al. (1935) papillae were also serially sectioned with the following result: in the age group 20 to 70 years there is an average of 208 taste buds per papilla but in the extreme age group 74 to 85 years there are only 88 taste buds per papilla.

Physiological behaviour

Several earlier authors (Ranvier 1888; Hermann, 1888; von Lenhossék, 1893/04; von Elner 1897) have, in their investigations of the structure of the taste buds, observed the occurrence of a varying number of leucocytes within the taste buds. This observation led to the thought that a steady degeneration of cells in the taste buds is taking place. However this degeneration is partly compensated for by simultaneous renewal.

Further support for this hypothesis has been obtained through Hermann's (1888) discovery of mitoses in the lower part of the taste buds. Kolmer (1910), Retzius (1912) and Heidenhain (1914) also supposed that a continuous transformation is taking place in the cells of the taste buds.

It is, however, through the studies of Beidler et al. (1960) Beidler (1961, 1962), Beidler and Smallman (1965) and Robbins (1967) on animals definitely proved that the cells in the taste buds pass a continuous process of degeneration and renewal. Beidler et al. injected colchicine, a mitosis inhibitory substance intraperitoneally into rats and then killed the animals and

In newborns sometimes there are taste buds on top of the papillae (Hoffmann 1875 Tuckerman 1880/90 Gråberg 1898 Jurisch 1922 Schumacher 1927).

Solitary or smaller groups of taste buds can be found embedded in the epithelium on various places in the oral cavity or the pharynx. Thus Hoffmann (1875) and Parker (1922) found taste buds on the soft palate above the uvula. In spite of serial sections however von Ebner (1891) Patzelt (1924) and Cairns (1955) could not find any taste bud like structures in this area.

Ponzo (1905) Patzelt (1924) and Mark (1940) have found taste buds on the posterior wall of the pharynx on the glossopalatine arch and on the epiglottis.

In the fetus, Patzelt (1924) has found taste buds in the orifice to the esophagus. Schinkele (1942) and Barkl (1953/54) have described taste bud like structures in the middle part of the esophagus.

Taste buds seem in general to be fully developed at birth and with

advancing age there is steady reduction of the number of papillae and also of taste buds. The fungiform papillae occur over the greater portion of the tongue: anterior two thirds during the latter part of fetal life or the earliest months of life. They are later greatly reduced in numbers.

No quantitative estimations of the number of taste buds situated on the fungiform papillae are available (Hoffmann 1870 Sistr 1902 von Skramlik, 1925 Schumacher 1927).

It is mainly the circumvallate papillae that have been the object of study first because they are easy to find on the tongue and secondly because they are few in number. In the adult, as earlier stated taste buds occur on the lateral sides of the papillae and the inside of the wall while in the newborn taste buds have been described also on the top of the papillae. The taste buds on the top, atrophy or disappear as a result of the continual wear of the tongue against the palate when sucking, swallowing and crying. Individual variations with regard to the number of papillae, their size and shape cause great difficulties when estimating the number of taste buds during different periods of life. Von Wya (1870) calculated the number per papilla at 400 Krause (1866) at 2500 and Gröberg (1890) at 100 to 150.

Through Heiderich's (1906) and Arey's et al. (1935) investigations, it has become evident that the taste buds are passing a progressive involution. Heiderich (1906) could by serial sectioning of the circumvallate papillae from individuals between 0 and 20 years of age, estimate the number of taste buds to an average of 248 per papilla. This figure is remarkably constant for all ages. In the work of Arey et al. (1935) papillae were also serially sectioned with the following result: in the age group 20 to 70 years there is an average of 208 taste buds per papilla but in the extreme age group 74 to 85 years there are only 88 taste buds per papilla.

Physiological behaviour

Several earlier authors (Ranvier 1868 Hermann, 1888 von Lenhossek 1892 '94 von Ebner 1897) have, in their investigations of the structure of the taste buds, observed the occurrence of a varying number of leucocytes within the taste buds. This observation led to the thought that a steady degeneration of cells in the taste buds is taking place. However this degeneration is partly compensated for by simultaneous renewal.

Further support for this hypothesis has been obtained through Hermann's (1888) discovery of mitoses in the lower part of the taste buds. Kolmer (1910) Retzius (1912) and Heidenhain (1914) also supposed that a continuous transformation is taking place in the cells of the taste buds.

It is, however through the studies of Beldier et al. (1900) Beldier (1901 1903) Beldier and Smallman (1905) and Robbins (1907) on animals definitely proved that the cells in the taste buds pass a continuous process of degeneration and renewal. Beldier et al. injected colchicine a mitosis inhibitory substance intraperitoneally into rats and then killed the animals and

studied the taste organs histologically. They found very many cells with mitotic division around the taste buds, but none inside them. The highest number of cells with mitotic division was reached after 6 hours and after about 12 hours it was normal again. Parallely a degeneration of the cells inside the taste buds took place. After 8 hours there was degeneration in only a few taste buds but after 48 hours there were degenerative changes to be found in the majority of taste buds.

Through these experiments it has been shown that the cells in the taste buds of rabbits undergo a degenerative process. In order to show that renewal of cells also is taking place, Beldler et al. injected labelled tritiated thymidine, which was "picked up by cells during their DNA synthesizing period prior to mitotic division" (Leblond et al., 1959). The tongue was prepared, sectioned and radio-autographed later with varying time intervals after the injection. These investigations show that the cells, which have divided in the periphery of the taste buds continuously wander to the center. A number of the cells never reach the center but degenerate before they reach it.

Beldler et al. estimated the life span of the cells to be about 250 ± 50 hours in rats. These experiments according to Beldler and others have shown that there is a continuous renewal of cells in the taste buds. De Lorenzo (1963 b) carried out similar investigations in rabbits and got the same results.

Fine structure of the taste buds

The taste buds consist of tightly placed ovoid bodies with slender cells. Their long axis generally lies at right angles to the surface layer of the epithelium on the papilla. They vary in size and also in form in different animal species as well as in different animals of the same species. Sometimes they are nearly round, sometimes oblong. At the base, which reaches the germinative layer of the epithelium, nerve fibers penetrate. The upper pole of the taste bud reaches the surface of the epithelium and is marked by an excavation, the taste pit, in which a number of slender microvilli are located. The taste buds mostly lie separately but sometimes they are more complex and may then have 2 or more pores.

Since Lovén's and Schwalbe's (1867) discovery of taste buds in higher animals a great number of publications have come out which deal with their structure and innervation.

Lovén (1867-1868) mainly studied the circumvallate papillae in calves but also in man. Taste buds or taste bulbs which Lovén proposed they should be called are, according to him, composed of 2 cell types: supporting or covering cells and taste cells. The latter are considered to be a special end organ and should constitute a direct continuation of the sensory nerve.

Schwalbe (1867-1868) who investigated taste buds from among other animals, horse, ox and sheep, also described 2 cell types under the same

name as Lörén. The taste cell ends in the pore in a hair like formation. Besides this taste cell Schwalbe found even another type called "Stäb-zellen" which reaches the pore without the hair-like formation.

Both Lörén and Schwalbe in their first works, believed that the covering or supporting cells were placed peripherally in the taste buds and surrounded the centrally situated sensory cells. Schwalbe, however reported (1887) that the supporting cells could occur inside the taste buds.

Hanvier (1888) described partly the inner and partly the outer supporting cells in the taste buds.

In 1888 Hermann showed that covering cells occur intermingled with the sensory cells and that there is yet another supporting cell, the basal cell, in the lower part of the taste bud.

Von Lenhossek (1893/94) could not verify basal cells in his examinations of taste buds from a rabbit's tongue. On the contrary he found 4 different forms of supporting cells peripherally situated in the taste bud and consequently not intermingled with the sensory cells. Only 1 type of sensory cell occurs and this is not to be understood as a continuation of the nerve.

Gräberg (1899) who studied taste buds from human tongues, observed 1 form of sensory cells and 3 different types of supporting cells, which, with regard to their position, were called central, peripheral and basal. The 2 first named supporting cells have the same structural formation and constitute the same type of cell, but with different localization in the taste bud. The basal cell, however differs from the others from a structural point of view. Gräberg, however could not clearly characterize the structural differences.

Many authors have earlier proposed that it is possible to differentiate between supporting and sensory cells. Kolmer (1910) for example described fibrils in the supporting cells. Between these "extremes" in the structure there were transitional forms, which, through their not so characteristic patterns, were difficult to group. The occurrence of these transitional forms could, according to Kolmer be an expression of a process, in which the cells were in different stages of function and development.

Retzius (1912) and Heidenhain (1914) agreed with Kolmer's opinion and further pointed out that taste buds should be regarded as a more uniform structure.

Ultra structure of the taste buds

After the basic histological investigations of the structure of the taste buds at the end of the nineteenth and the beginning of the twentieth centuries, no extensive work has been published, dealing with structural problems, until during the last decade when the electron microscopical reports have come. Kolmer (1927) has, however in "Handbuch der mikroskopischen Anatomie des Menschen" given a fairly thorough survey of the structure of the taste buds.

In 1950 Engström and Rylzner with a short interval published 2 electron microscopical works on the ultrastructure of the taste buds in the rabbit. In these works which are the earliest published 2 cell forms were described where one of them was slender with a little cytoplasm and the other more voluminous with a broad cytoplasm containing granules and vacuoles. All the cells reach to the taste pore and there end in a number of finger like projections villi. In spite of certain differences in the structure of the cells, the authors considered however that it was not possible to differentiate between sensory cells and supporting cells, but pointed out that it was quite possible that the cells could pass over from one form into another during their life-cycle.

Trujillo-Cendá (1957) also described only 1 type of cell in his electron microscopic study on the taste buds in rabbit.

De Lorenzo (1958, 1960, 1963 a) on the contrary distinguished sensory cells and supporting cells in the rabbit. The former which extend from the base of the taste bud to the taste pit have a dark nucleus with dense granular cytoplasm and end in the taste pit in microvilli. Supporting cells have a more diffusely granular nucleus and less dense cytoplasm with granules and vacuoles. These cells do not reach to the taste pore.

Like de Lorenzo Iriki (1960), Demetachek-Casler and Ferner (1964) found 2 well defined types of cells in the taste buds of rabbits with the same appearance as those described by de Lorenzo.

In an electron microscopy study on the taste buds in rats Farbman (1965 a) described from a morphological point of view 4 separate cell types, namely peripheral cells, basal cells, together with type I and type II cells. The peripheral cells are least differentiated and are considered to be precursors of the other types. These cells lack contact with intraepithelial nerve structures. From a morphological point of view the basal cells are similar to the peripheral but have contrary to the latter contact with nerve structures and in addition contain vesicles. The type I cells, the most numerous, were considered to constitute the taste receptors. As type I cells, the type II cells are also situated centrally in the taste buds and have contact with the intraepithelial nerve structures. Type II cells contain an abundance of vacuoles and vesicles and were considered to be significant for the formation of the taste pore.

The most thorough studies of the taste buds ultrastructure have been carried out by Murray and Murray who in 1960 reported an investigation in monkeys where the taste buds from the circumvallate papillae were studied. The structure of the individual cells can vary quite considerably but they are only of 1 type namely gustatory. Microvilli occur in the pore but they are not as conspicuous as in the rabbit. Murray presented in 1961 the result of electron microscopic studies of the taste buds of rabbits. 2 types of cells with gustatory function were described, partly more numerous slender dark cells with granules in the apical part and partly more

rarely occurring light vacuolised cells. Both cell types terminate in microvilli in the taste pit. In 1967 the result was published of the continued studies in a work where 200 taste buds from the foliate papillae in rabbits were studied. It was confirmed, that there exist 2 cell types. As in the work from 1961 the cells are described as "light" and "dark". They both contain fibrils in the cytoplasm, but, there are more in the "dark" cells. Both cell types terminate in villus-like projections into the taste pit. The "light" cells also have centrioles with rootlets but no kinocilium, which is considered as evidence that the cells have gustatory function. The "dark" cells are supporting "with possibly a gustatory function as well".

Innervation

The course of peripheral taste nerves has ever since the beginning of the nineteenth century been the object of interest from a clinical as well as experimental point of view.

Bellingeri (1818) was the first who described that the chorda tympani contains taste fibers, but as early as 1823 Magendie stated that the trigeminal nerve carries taste fibers. These early publications, however, are only the beginning of a discussion of the role of the facial and trigeminal nerves as origin of taste fibers.

Claude Bernard (1843) had, through clinical studies of patients with facial nerve palsy and by experimental investigations in dogs, noted that injury to the chorda tympani gave taste disturbances. The chorda tympani, however, was by Bernard considered to have a motor function. By stimulating the chorda tympani in human beings, who after various forms of surgical approaches to the middle ear or as a sequel to chronic otitis have had the nerve exposed, Duchenne (1850) and Blau (1879) created taste sensation on the anterior two thirds of the tongue. Further support for the view that the chorda tympani carried taste fibers from the anterior parts of the tongue comes through investigations of Gazot and Cazeils (1839) and Biffi and Morpanis (1845). Today there exists unanimous agreement that the chorda tympani mainly carries taste impulses from the anterior two thirds of the tongue.

Regarding the further course of the taste pathways, some of the most important opinions will be discussed in the following section.

The chorda tympani follows in its most peripheral course the lingual nerve. In the infratemporal fossa it leaves this nerve and continues alone toward the base of the skull, passes the middle ear and joins the facial nerve in the Fallopian canal, as a rule proximal to the stylomastoid foramen (Gray 1933, Jeppsson 1967). The taste fibers follow the facial nerve to the geniculate ganglion, after which, via nervus intermedius, they reach the nuclei in tractus solitarius (Lusana, 1869; Dixon, 1897; Cushing, 1903; Lewis and Dandy 1930; Carmichael and Woodard, 1933; Zolterman 1935; Weingarten and Gloning, 1954; Mackenzie 1935; Krarup, 1938; b; Feldmann

and Maler 1959 Carco, 1959 Pulec et al., 1964 Krarup 1965 Motta et al 1964 Pascher and Fischer 1968)

The taste fibers from the chorda tympani can also run via the various branches of the trigeminal nerve in a central direction. Some authors (Erh, 1875 Gowers, 1897 Talo and Sebastian 1955 Motta et al 1964) have reported the following pathways as probable for the taste fibers. From the geniculate ganglion the taste fibers go to the sphenopalatine ganglion via the great superficial petrosal nerve and further through the maxillary nerve to the semilunar ganglion

Others (Gowers 1897 Ziehl 1889 Krause 1895) on the contrary considered that the taste fibers run from the geniculate ganglion to the otic ganglion via the small superficial petrosal nerve and then in the mandibular nerve to the semilunar ganglion

While the majority of authors have considered the chorda tympani as the nerve which supplies the anterior part of the tongue others (Eulenburg 1871 Godskesen 1888 Luciani 1911 Tschinazy 1950) contend that the glossopharyngeal nerve alone carries the taste fibers in a central direction from the whole tongue. Thus the taste fibers should run in the following way via the chorda tympani to the geniculate ganglion and further via the small superficial petrosal nerve over anastomoses to the tympanic plexus and Jacobson's nerve to the glossopharyngeal nerve

The posterior third of the tongue is generally considered to be supplied by the glossopharyngeal nerve

Taste buds situated in the pharynx and larynx are innervated by the vagus nerve.

The gustatory afferent pathways ipsilaterally lead to nuclei in tractus solitarius where the secondary gustatory neuron is situated (Blomquist and Antem 1963 1967) From tractus solitarius they however continue in the opposite ascending medial lemniscus to the arcuate nucleus of thalamus

It is mainly through electrophysiological studies either by the preference method or by recordings from various levels in the taste area it has been possible definitely to elucidate the taste pathways (Blum et al 1943 Patton et al 1944 Andersson and Jewell 1957 Benjamin and Akert 1959 Oakley and Pfaffmann 1962 Bradley 1963)

There are very few clinical reports on tumours in the thalamus (Adler 1935 Gänshirt 1950) or injuries (Weingarten and Cloning 1954) with taste disturbances. The earlier opinion was that the cortical representation of taste and smell is situated in the same area of uncus and gyrus hippocampi. Through Börstein's work (1928, 1940 a) however it is agreed that the central projection of taste is at the lower portion of gyrus pre- and postcentralis. Börstein's result has been verified by electrophysiological investigations. In these experiments the chorda tympani was stimulated and the evoked potentials in the cortical centers were studied (Bremer 1923 b, Patton and Amassian 1952 Benjamin and Pfaffmann 1955 Cohen et al

1937 Landgren, 1947 Benjamin and Akert, 1959 Benjamin and Emmers, 1960 Landgren et al., 1967) These studies showed that the central projection of taste is not separately located, but it is within the tactile projection area of the tongue. There also are some investigations with the preference method and these also support the opinion that the taste center is situated around gyrus pre- and postcentralis (Blum et al. 1943 Bagshaw and Pribram 1953).

Shenkln and Lewey (1944) Weingarten and Glosning (1934) reported taste disturbances in patients with cerebral injuries or tumours within the supposed taste centers.

Penfield and Boldrey (1937) could create taste sensations in patients, in whom they stimulated cortical areas of gyrus pre- and postcentralis.

It can thus be stressed that the taste buds on the fungiform papillae on the anterior two thirds of the tongue are innervated by the chorda tympani and that those on the circumvallate papillae and the foliate papillae on the posterior third of the tongue are innervated by the glossopharyngeal nerve. In man, and also rabbit the innervation from both the nerves is homolateral. Chorda tympani is considered, however to have a certain overlapping on the tip of the tongue (Zander 1897 Wlberg, 1967 1969).

Intragemmal nerve structures

In the earliest studies concerning the innervation of the taste buds, the sensory cells were considered to be a direct continuation of the nerve penetrating the taste buds (Loren, 1867 1868 Schwalbe 1867 1868 Fusari and Panuaci 1889/90). By nerve staining technique the innervation pattern could be charted in another way and in earlier opinion refuted (Retzius, 1892 von Lenhossek, 1892/03 Arnstein 1893). Their results are in the main, in agreement with our present opinion about the innervation of the taste buds (Holmer 1927 Kadanoff 1963 Bloom and Fawcett, 1968). Just below the taste buds is a tortuous nerve plexus and from this run branches, partly to the inside of the taste buds, intragemmally partly to the epithelium between the taste buds, intergemmally. The latter fibers also can envelop the taste bud and are then named perigemmal. The nerves divide repeatedly in their course towards the surface of the epithelium and often exhibit small terminal enlargements. Nerve fibers have been observed running intragemmally as far as to the region of the taste pit.

The contact between the sensory cell and the nerve has, through electron microscopy studies been shown to occur in a synaptic way (Engström and Rylander 1958 a, b Trujillo Cenda, 1957 de Lorenzo, 1958, 1960 Iriki, 1960 Murray and Murray 1960 1967 Nemetschek-Gansler and Ferner 1964 Cray and Watkins, 1963 Farthman, 1964 a) Gray and Watkins (1965) the authors who most thoroughly studied the synaptic regions of the taste buds, point out, however that "membrane specialisations differ from the membrane thickenings of other types of synapse. Presynaptic dense projec-

and Valer 1959 Carco 1959 Pulec et al., 1964 Krarup 1965 Motta et al., 1964 Pascher and Fischer 1968)

The taste fibers from the chorda tympani can also run via the various branches of the trigeminal nerve in a central direction. Some authors (Erb, 1875 Gowers 1897 Talo and Sebastian 1955 Motta et al. 1964) have reported the following pathways as probable for the taste fibers. From the geniculate ganglion the taste fibers go to the sphenopalatine ganglion via the great superficial petrosal nerve and further through the maxillary nerve to the semilunar ganglion.

Others (Gowers, 1897 Ziehl 1889 Krause 1895) on the contrary considered that the taste fibers run from the geniculate ganglion to the otic ganglion via the small superficial petrosal nerve and then in the mandibular nerve to the semilunar ganglion.

While the majority of authors have considered the chorda tympani as the nerve which supplies the anterior part of the tongue others (Eulenburg 1871 Godskesen 1888 Luciani 1911 Tschlössner 1950) contend that the glossopharyngeal nerve alone carries the taste fibers in a central direction from the whole tongue. Thus the taste fibers should run in the following way via the chorda tympani to the geniculate ganglion and further via the small superficial petrosal nerve over anastomoses to the tympanic plexus, and Jacobson's nerve to the glossopharyngeal nerve.

The posterior third of the tongue is generally considered to be supplied by the glossopharyngeal nerve.

Taste buds situated in the pharynx and larynx are innervated by the vagus nerve.

The gustatory afferent pathways ipsilaterally lead to nuclei in tractus solitarius, where the secondary gustatory neuron is situated (Blomquist and Antem 1965 1967). From tractus solitarius they however continue in the opposite ascending medial lemniscus to the arcuate nucleus of thalamus.

It is mainly through electrophysiological studies either by the preference method or by recordings from various levels in the taste area it has been possible definitely to elucidate the taste pathways (Blum et al. 1943 Patton et al., 1944 Andersson and Jewell 1957 Benjamin and Akert 1959 Oakley and Pfaffmann 1962 Bradley 1963).

There are very few clinical reports on tumours in the thalamus (Adler 1935 Gänshirt 1950) or injuries (Welingarten and Cloning, 1954) with taste disturbances. The earlier opinion was that the cortical representation of taste and smell is situated in the same area as uncus and gyrus hippocampi. Through Börnstein's work (1928 1940 a) however it is agreed that the central projection of taste is at the lower portion of gyrus pre- and postcentralis. Börnstein's result has been verified by electrophysiological investigations. In these experiments the chorda tympani was stimulated and the evoked potentials in the cortical centers were studied (Bremer 1923 a 1 Patton and Amassian 1952 Benjamin and Pfaffmann 1955 Cohen et al.,

were transported away by phagocytes. The place of the cover-cells was taken by epithelial cells.

In earlier reported works, after the transection of the glossopharyngeal nerve, changes in the taste buds were found. Later however Baginsky (1893, 1894) repeated the experiment but could not see any changes of a degenerative nature or a disappearance of taste buds, despite an observation time of between 3 and 57 days. He pointed out that on the side of the tongue where the function of the nerve was the same as in normal animals, changes could be observed of the same nature which earlier authors had thought to be dependent upon nerve injury. Microscopical examinations of the nerves in the peripheral regions, showed pronounced degenerative changes in the ganglionic cells and the protoplasm contained an abundance of granules. According to Baginsky's opinion however these changes could not be assigned any greater value.

The inside of the tongue is innervated by 2 nerves, the glossopharyngeal nerve and the chorda tympani. All earlier experiments refer to the excision of the glossopharyngeal nerve. There are, however a number of studies, in which the chorda tympani has been cut off selectively or in its common course with the lingual nerve. In the year 1917 Boeke reported an investigation where he had divided the lingual nerve in hedgehogs and saw degeneration of the papillae with taste buds on the ipsilateral anterior half of the tongue.

By the excision of the lingual nerve in dogs, Olmsted (1921) showed that the taste buds disappeared through a degenerative process. Phagocytizing leucocytes were observed in the taste buds. The breakdown products were also presumed to be pushed out through the taste pore. Epithelial cells replaced the taste buds and in the germinal layer there appeared a considerable number of mitoses. Olmsted (1922) also carried out a selective excision of the chorda tympani in dogs and got the same result. In studies of the innervation of the tongue muscles in cats, Langworthy (1924) reported that after excision of the lingual nerve no taste buds could be observed on the anterior parts of the tongue.

With the intention of mapping out the innervation areas of the various taste nerves in rats, Whiteside (1927) carried out excision of the glossopharyngeal nerve and the chorda tympani. He found that excision of the glossopharyngeal nerve only caused a total disappearance of taste buds in the posterior furrows of the foliate papillae while in the anterior furrows a number of intact taste buds could be observed. However if he at the same time carried out division of the chorda tympani on the same side he got complete disappearance. In rats, then, contrary to rabbits, the foliate papillae's anterior portion is innervated by both the glossopharyngeal nerve and the chorda tympani. The circumvallate papillae are innervated bilaterally by the glossopharyngeal nerve while the fungiform papillae are supplied by the chorda tympani. The degeneration of the taste buds started

tions are present but there is no well defined postsynaptic thickening. Vesicles occur in both pre- and postsynaptic components, but it is debatable whether or not they should be termed synaptic vesicles"

Ganglion cells have been found under the tongue papillae (von Lenhossék 1893/94 Merkel 1917 Kolmer 1927 Iwayama and Nada 1967 a, b Bloom and Fawcett 1968) The possibility has been brought up that the taste buds have an autonomic innervation (Kolmer 1927 Desgranges, 1966)

b The taste organ after transection of gustatory nerves

By means of earlier experimental investigations it has been found that the receptor organs for taste, the taste buds degenerate after severance of the nerves which belong to them.

The first investigations were carried out by von Vintschgau and Hönigschmied (1876) who in 2 rabbits excised the glossopharyngeal nerve on one side of the neck and after 5 months killed the animals. The foliate and circumvallate papillae were dissected out fixed in 1 % osmic acid and then examined. Macroscopically there were no certain changes. The microscopic examination revealed that the normal number of taste buds were found on the unoperated side, while in the operated side practically all the taste buds had disappeared. In the one animal the furrows in the foliate papillae were more shallow on the operated side than on the unoperated side.

In 1880 von Vintschgau published a further work on rabbits in which he had carried out the excision of the glossopharyngeal nerve and killed the animals at various intervals after the operation. On examination no changes in the taste buds were observed within the first 24 hours, while clear changes were seen already after the first 2 days. Certain taste buds situated more deeply seemed bigger than others and so-called "Deckzellen" furnished with granules had begun to lay themselves against the epithelial cells. The changes in the sensory cells could not be evaluated. During the 2nd and 3rd day there were also seen changes in the more superficially situated taste buds and all the forms were transitory between normal and wholly disorganized taste buds. The degenerative process continued and after 7 days a considerably reduced number of taste buds existed. After 3 weeks no certain taste buds could be found. Von Vintschgau's impression was that "Deckzellen" had been transformed to epithelial cells. He had not come to any decision regarding the disappearance of the taste cells.

Griffini (1884 1887) Drasch (1887) Ranvier (1888) Sandmeyer (1895) and Meyer (1896) by means of similar experiments confirmed the results of earlier investigations. But contrary to von Vintschgau and Hönigschmied they saw a complete disappearance of the taste buds. Ranvier felt that the sensory cells degenerated and the breakdown products

were transported away by phagocytes. The place of the cover-cells was taken by epithelial cells.

In earlier reported works after the transection of the glossopharyngeal nerve changes in the taste buds were found. Later however Baginsky (1893, 1894) repeated the experiment but could not see any changes of a degenerative nature or a disappearance of taste buds, despite an observation time of between 3 and 87 days. He pointed out that on the side of the tongue where the function of the nerve was the same as in normal animals, changes could be observed of the same nature which earlier authors had thought to be dependent upon nerve injury. Microscopical examinations of the nerves in the peripheral regions, showed pronounced degenerative changes in the ganglionic cells and the protoplasm contained an abundance of granules. According to Baginsky's opinion however these changes could not be assigned any greater value.

The inside of the tongue is innervated by 2 nerves, the glossopharyngeal nerve and the chorda tympani. All earlier experiments refer to the excision of the glossopharyngeal nerve. There are, however a number of studies, in which the chorda tympani has been cut off selectively or in its common course with the lingual nerve. In the year 1917 Boeke reported an investigation where he had divided the lingual nerve in hedgehogs and saw degeneration of the papillae with taste buds on the ipsilateral anterior half of the tongue.

By the excision of the lingual nerve in dogs, Olmsted (1921) showed that the taste buds disappeared through a degenerative process. Phagocytizing leucocytes were observed in the taste buds. The circumvallate papillae are innervated bilaterally by the glossopharyngeal nerve while the fungiform papillae are supplied by the chorda tympani. The degeneration of the taste buds started

tions are present but there is no well defined postsynaptic thickening. Vesicles occur in both pre- and postsynaptic components, but it is debatable whether or not they should be termed synaptic vesicles.

Ganglion cells have been found under the tongue papillae (von Lenhossek 1893/94, Merkel 1917, Kolmer 1927, Iwayama and Nada 1967 a, b, Bloom and Fawcett, 1968). The possibility has been brought up that the taste buds have an autonomic innervation (Kolmer 1927, Desgranges, 1966).

b The taste organ after transection of gustatory nerves

By means of earlier experimental investigations it has been found that the receptor organs for taste, the taste buds, degenerate after severance of the nerves which belong to them.

The first investigations were carried out by von Vintschgau and Honigsmied (1870) who in 2 rabbits excised the glossopharyngeal nerve on one side of the neck and after 5 months killed the animals. The foliate and circumvallate papillae were dissected out, fixed in 1 % osmic acid and then examined. Macroscopically there were no certain changes. The microscopic examination revealed that the normal number of taste buds were found on the unoperated side, while in the operated side practically all the taste buds had disappeared. In the one animal the furrows in the foliate papillae were more shallow on the operated side than on the unoperated side.

In 1880 von Vintschgau published a further work on rabbits in which he had carried out the excision of the glossopharyngeal nerve and killed the animals at various intervals after the operation. On examination no changes in the taste buds were observed within the first 24 hours, while clear changes were seen already after the first 2 days. Certain taste buds situated more deeply seemed bigger than others and so-called "Deckzellen" furnished with granules had begun to lay themselves against the epithelial cells. The changes in the sensory cells could not be evaluated. During the 2nd and 3rd day there were also seen changes in the more superficially situated taste buds and all the forms were transitory between normal and wholly disorganized taste buds. The degenerative process continued and after 7 days a considerably reduced number of taste buds existed. After 3 weeks no certain taste buds could be found. Von Vintschgau's impression was that "Deckzellen" had been transformed to epithelial cells. He had not come to any decision regarding the disappearance of the taste cells.

Griffiths (1884, 1887), Dransch (1887), Ranvier (1888), Sandmeyer (1895) and Meyer (1896) by means of similar experiments, confirmed the results of earlier investigations. But contrary to von Vintschgau and Honigsmied they saw a complete disappearance of the taste buds. Ranvier felt that the sensory cells degenerated and the breakdown products

a de-differentiation or metamorphic transformation process occurs and imply that the so-called "Deckzellen" changes into common epithelial cells. Whether the taste cells are changed or not cannot be stated with certainty. Some authors (Ranvier 1888 Olmsted 1921 Whiteside 1927 Guth, 1937) have found proof that the taste buds disappear through a degenerative process. Ranvier (1888) has given the earliest and most detailed description of this process. The cells in the taste buds are disorganized, they degenerate and are phagocytized by leucocytes. Some of the break down products are also pushed out through the pores, which are considered to be the last structures to disappear. The taste buds are replaced by epithelial cells. Mitoses have been observed in the germinative layer.

According to Olmsted (1920 a) May (1925) and Torrey (1934) there is a neurohumoral substance in cat-fish which constitutes the trophic factor between nerve and taste bud. The authors divided the taste nerves in the cat fish and got degeneration of the taste buds. The course of events was not similar to those in warm-blooded animals. The taste buds were intact for some days and then rapidly degenerated in one day. The authors felt that these events proved their hypothetical assumption of a neurohumoral substance. This substance occurs in the peripheral nerve stump and is consumed within a certain period of time. The time however is influenced by the temperature and the length of the peripheral nerve stump.

Whiteside (1927) and Guth (1937) have discussed the hypothesis of the neurohumoral factor in their reports of experiments on rats. These authors point out that the course of degeneration is quite different. The degenerative process goes on from the first day after the excision and up to a week until it is finished. In conclusion it can be stated that there is a fundamental difference in the relation between nerves and taste buds in warm-blooded and cold-blooded animals.

c. The taste organ after suture of gustatory nerves

There are only a few reports about the regeneration of taste buds after injuries to the taste nerves. The problem in the studies of regeneration has as a rule been whether the taste buds can reform after reinnervation of only gustatory or only non-gustatory nerves.

Olmsted and Pinger (1930) and Arey and Monzingo (1942) have on the tongues of dogs, shown taste buds after reinnervation of the lingual nerve. The same result is obtained by Guth (1938) on cats when he carries out end-to-end anastomosis of the transected glossopharyngeal nerve or between the central portion of the vagus nerve which contains gustatory fibers, and the distal portion of the glossopharyngeal nerve or vice versa. The result when only gustatory nerves are sutured is thus identical.

On the other hand the result diverges in an experiment where the central

4 to 5 days after the operation and was completed in 3 weeks after which time no taste buds could be found

In 1942 Hayes and Elliott published a work on the excision of the lingual nerve in cats. The authors stated that in the cat as in man the anterior two thirds of the tongue was innervated by the chorda tympani and the tip of the tongue was innervated from both sides like the area just in front of the circumvallate papillae

Guth (1957) also used rats as experimental animals in his study. Bilateral excision of the glossopharyngeal nerve was carried out and histological investigation of the circumvallate papillae undertaken. As shown by many earlier authors, a degeneration of the taste buds occurred. The changes which appeared in the epithelium were also studied by Guth. He found that the epithelium over the circumvallate papillae was reduced to a third or more of its original thickness. This reduction was evenly distributed over the whole surface of the papilla and not only in the area where taste buds previously had been found.

Already in 1927 Whiteside had shown that the circumvallate papillae in rats was innervated by the glossopharyngeal nerve from both sides. With the support of these results Guth (1963) carried out unilateral and bilateral excision of the glossopharyngeal nerve to study the effect of partial and total denervation. Guth kept calculations of the number of taste buds per section and determined the thickness of the epithelium both 7 and 35 days after the operation. Unilateral excision of the glossopharyngeal nerve caused a statistically significant reduction of the number of taste buds by 12 %. In determining the number of cells per taste bud there was a reduction up to 25 %. Bilateral excision caused a complete loss of taste buds. The epithelium was also considerably reduced. The same values were found in calculations carried out 7 and 35 days postoperatively. Bilateral excision gave a total loss of taste buds within 7 days and also more noticeable atrophy of the epithelium on the operated side as compared with the intact side. These findings would indicate that the taste buds are bilaterally innervated and every nerve fiber supplies a number of cells. Beldler (1963) injected alcohol into the middle ear of rats with the intention of injuring the chorda tympani. As early as 4 to 8 hours later the taste buds became smaller and after 96 hours there were only a few taste cells but no taste pores. After 7 days all the taste buds had disappeared.

Olmsted (1920 a), May (1925) and Torrey (1934, 1936) divided the nerve to "the barbel" of a cat fish *Amelurus* which contains taste buds and got complete degeneration after 10 to 12 days.

From the above comparison of experimental investigation by transection of the taste nerves in mammals it is clear that after a certain time a total loss of taste buds occurs both in mammals and fish. The way in which this takes place, has been discussed by some authors. Others only confirm that it has taken place. Von Vintschgau (1880) and Meyer (1896) consider that

a de-differentiation or metamorphic transformation process occurs and imply that the so-called "Deckzellen" changes into common epithelial cells. Whether the taste cells are changed or not cannot be stated with certainty. Some authors (Ranvier 1888, Olmsted, 1921, Whiteside 1927, Guth, 19) have found proof that the taste buds disappear through a degenerative process. Ranvier (1888) has given the earliest and most detailed description of this process. The cells in the taste buds are disorganized, they degenerate and are phagocyted by leucocytes. Some of the broken down products are also pushed out through the pores, which are considered to be the last structures to disappear. The taste buds are replaced by epithelial cells. c. The taste organ after suture of gustatory nerves

There are only a few reports about the regeneration of taste buds after injuries to the taste nerves. The problem in the studies of regeneration has as a rule been whether the taste buds can reform after reinnervation of only gustatory or only non-gustatory nerves.

Olmsted and Pinger (1938) and Arey and Moaxingo (1942) have on the tongues of dogs, shown taste buds after reinnervation of the lingual nerve. The same result is obtained by Guth (1938) on cats when he carries out end-to-end anastomosis of the transected glossopharyngeal nerve or between the central portion of the vagus nerve, which contains gustatory fibers, and the distal portion of the glossopharyngeal nerve or vice versa. The result when only gustatory nerves are sutured is thus identical.

On the other hand the result diverges in an experiment where the central

portion of a non-gustatory nerve is joined to a gustatory distal portion Boeke (1917) has on hedgehogs and Olmsted and Pinger (1936) on dogs, shown taste buds after anastomosis between the hypoglossal nerve and the lingual nerve while Arey and Monzingo (1942) on dogs, and Guth (1958) on cats did not obtain new formations of taste buds in spite of long periods of observation. In all the investigations it is pointed out that immediately postoperatively there is a total disappearance of the taste buds.

Oakley (1967) in rats carried out end-to-end anastomosis between the lingual and glossopharyngeal nerves. After about 15 weeks electrophysiological recordings were performed on the reinnervated nerves. By chemical stimulation of the receptor organ a summated nerve response resembling that of the distal anastomosis portion is obtained. The author draws the conclusion partly that a reinnervation has occurred and partly that a regeneration of the taste buds has taken place. No histological examination is reported however.

Griffith (1887) and Whiteside (1926) after experimentally created local injury to the tongue where the innervation is intact show that taste buds develop on regenerated taste papillae.

II MATERIAL AND ANIMAL EXPERIMENTS

Rabbits have been used as experimental animals. They have well developed bilateral foliate papillae on the posterior lateral area of the tongue. These papillae are distinctly delimited and contain a large number of taste buds, which are innervated by the glossopharyngeal nerve (N IX). In order to produce degeneration of the taste buds transection of this nerve is carried out and regeneration is initiated by suturing the divided nerve.

A large number of taste buds from other animals notably monkeys have been studied in order to compare the normal structure of different animals. The results of the studies of the other animal species is not included in the following report but has been used as a comparison during the course of this work.

The total number of rabbits used was 90 and of these 53 have been used for the analysis of the normal structure. 38 were used for the study of degeneration in connection with nerve severance and the other 19 rabbits comprise the group containing the sutured glossopharyngeal nerves. The weight of these rabbits at the beginning of the experiment was between 1.2 kg and 2 kg.

Preparation of the foliate papillae

In the beginning of this study the animals were killed by an air embolus. The tongue was then immediately removed and the region with the foliate

papillae was excised and divided into suitable pieces for fixing. It was apparent however that the above method did not give good results so the procedure was changed. Instead of killing the animal immediately it was anaesthetized with mebumal-sodium (8%) and the corner of the mouth clipped up to give a better view of the back of the tongue. The jaws were held apart with a clamp and the area with the foliate papillae became fairly easily accessible. The papillae were then excised and divided into suitable pieces for fixing. In most cases the papillae were bent apart from one another and a number of incisions were made at right angles and also parallel with the long axis of the papillae. In this way the solution penetrated more rapidly down into the submucous tissues.

The specimens were, as a rule, fixed in veronal-buffered 1.5 % osmic acid solution for 2 hours, followed by a washing in physiological saline. They were then dehydrated in increasing concentrations of alcohol and propylenoxide. The specimens were then embedded in epoxy resin (Epon 812) or acrylic.

In 5 rabbits during the later part of the investigation, the specimens were fixed in a phosphate-buffered 2.5 % glutaraldehyde solution (pH 7.5). The solution was perfused through the common carotid artery for 10 minutes. It was possible to verify that the solution had passed into the tissue by the appearance of a yellow color in the mucous membrane in the oral cavity. When the perfusion was finished, the papillae were excised in the same way as described above. After 6 to 8 hours the specimens were post fixed in veronal buffered 1.5 % osmic acid solution and then dehydrated and embedded in epon.

In 7 cases the specimens were fixed and stained according to Mallet's modified zinc-iodine method (AZ staining, Engström et al. 1966). The specimens were fixed 8 to 10 hours and rinsed and dehydrated before embedding. These embedded specimens were sectioned with glass knives in an LKB Ultratome and then the sections were studied in light and phase contrast microscopy (Wild research microscope M 20 with camera). The film material Kodak Tri X Pan 120 was used. The same microtome was used for preparing the sections for electron microscopy. The sections which were examined in the light and phase contrast microscope are stained in a solution of pararosanilin (Estable-Puig et al. 1965). The sections for electron microscope are stained in uranyl acetate and lead citrate and examined in a Siemens Elmiskop 1A.

Transection of the glossopharyngeal nerve

The transection of the glossopharyngeal nerve was performed on rabbits anaesthetized with mebumal-sodium (8 %). Injected either intraperitoneally or through a marginal vein at the ear. In order to reduce bleeding in the operation area, xylocain-exadrim (0.5 %) was injected locally. The operation was in all cases carried out on the right side of the neck with the most sterile

Fig 1 Lateral view of the neck of a rabbit after skin incision. The styli pharyngeal muscle has been divided and the course and relation to other structures of the glossopharyngeal nerve (N IX) can be seen. Note the small branch (arrow) of the glossopharyngeal nerve. Low power magnification.

conditions possible. When a suitable depth of anaesthesia had been attained the fur was cut and incision was made just below and parallel with the lower jaw. Through blunt dissection through the muscles on the neck which are against the base of the skull the glossopharyngeal nerve was identified. The nerve was followed peripherally where it runs medially and somewhat cranially to the hypoglossal nerve. About 1 cm below its departure from the jugular foramen on the base of the skull a branch of the glossopharyngeal nerve leaves and runs parallel to the main nerve in a peripheral direction (Fig 1). The division of the nerve was carried out about 5 mm below the base of the skull and 2 to 3 mm of the nerve was excised. It was of the greatest importance that the bifurcation of the nerve be dissected out before the excision. In this way no branch could be left by performing the excision in too peripheral a manner. The operation was carried out under a microscope and very slender instruments were used. Generally no appreciable bleeding occurred during the operation. The skin was sutured with nylon thread and no postoperative wound infection was noted. Those animals which were supposed to survive for a longer time were put into their cages; the rabbits increase in weight in the normal way.

Suture of the glossopharyngeal nerve

The procedure of the experiment of nerve suture was identical with the foregoing until the glossopharyngeal nerve was dissected out. In order to get a better view of the nerve and a greater area in which to work the stylopharyngeal muscle was divided. The nerve division was proximal to the site of branching. The operation was carried out under a microscope and generally under 25x magnification. This division must be done with careful dissection so that the circulation around the nerve will not be disturbed. The free stumps were separated to make certain that all the fibers were sectioned. Thereafter the stumps were brought together and sutured with a silk suture (Ethicon 8/0). The divided muscle and skin were sewn up. No postoperative infection was noted. The animals grew and increased normally in weight.

At the end of the experiment, the animals were killed by a plan previously decided upon, and the foliate papillae were excised and prepared in the manner described above.

III. RESULTS

a. The normal structure

As pointed out earlier the furrows in the peripheral parts of the foliate papillae region are shallow while the central region has deeper furrows. In order to get uniformity in the material investigated and to be able to correctly appreciate both the normal and pathological structures, in the main, the central parts within the papillae have been examined. The aim has been to work with corresponding areas in each of the papillae.

The foliate papillae

The foliate papillae consist of a number of ridges or lamellae and furrows. These furrows contain the taste buds. The area with papillae can vary in human size. The surface of the papillae is covered with stratified squamous epithelium. The epithelium as a rule projects down in the stroma of the ridges like two wedges, which after sectioning at right angles to the direction of the lamellae gives the appearance of pseudopapillae. The stroma in the papillae consists of connective tissue, fat, nerves and blood vessels. Centrally in every lamella there is a sinusoid like vessel (Fig. 2).

In the epithelium, the taste buds (Fig. 3) are situated with the top or the taste pit, toward the furrow and the base toward the stroma of the papillae. The taste buds are situated only on the surface opposite the furrow and no taste buds on top of the lamellae were observed. Within the central parts of the papillae ridges occasionally occur which are partly but not wholly lacking in taste buds. However the absence of the taste buds is more common in the peripheral areas.

Fig 2 Central part of a foliate papilla with ridges and furrows. The taste buds are situated in the epithelium against the furrows. Nerve profiles appear not only subepithelially but also deeper in the core of the papilla. Centrally the ridges contain a sinusoid vessel (arrow). Note the epithelial projections into the core of the papilla giving a pseudopapillary appearance. Phase contrast microscopy 100 x

The taste buds

The taste buds have a relatively uniform shape and appearance in the mouth. In light and phase contrast microscopy they appear as lighter (Fig 3) oviform formations in the somewhat darker and denser epithelium. The cells of the taste buds generally reach from the basement membrane to the small taste pit through a taste pore which opens into the surface of the tongue. This implies that the individual cells are rather high and slender while those in the central part are nearly cylindrical. On the contrary those situated on the periphery of the taste bud often appear in the histological section to be sickle-shaped. The taste bud is surrounded by the squamous epithelial cells of the tongue which are rich in tonofibrils and contain large numbers of desmosomes. These desmosomes generally make it easy to distinguish "gemmal" and "nongemmal" epithelial cells. The taste pore is seen as an opening in this dense layer of squamous epithelial cells. At the base of the taste bud a number of unmyelinated nerves penetrate. These nerve fibers form a rich plexus of chiefly unmyelinated

All figures are from specimens of rabbit fixed osmically (1.5 %)

Fig. 1. Taste bud, normal, with the taste pit at the top and the nerve entrance at the base. The nucleus of the light cell is round and that of the dark cell is oblong. nated fibers just below the taste bud. Some of them come from the perigemmal areas situated between the taste buds.

In rabbits, the cells within the taste buds vary quite considerably in structure and there is great difficulty in differentiating the various cell types from one another. Sometimes it can even be difficult to distinguish neural elements from the taste bud cells. This applies above all to those nerve fibers reaching the proximity of the pore.

It has not, in this investigation, been possible to decide whether or not perigemmal cells can be transformed to gemmal. It is clear however after studying a large number of taste buds, that many different varieties of cell forms, of cell density and of cell inclusions can occur in the taste buds of the rabbit.

In light microscopy taste bud cells usually appear lighter than the surrounding squamous epithelial cells. Within the individual taste buds the cells vary in form and shape in a manner which encourages classification into light and dark cells. The same difference appears in phase contrast microscopy when studying specimens embedded in epon and stained with pararpyrendiamin solution. The distribution of light and dark cells varies considerably. It seems that cell degeneration and cell breakdown affect the light cells first. It can now be established that through this investigation it has not been possible to distinguish 2 completely different forms of cells in the taste buds. However all variations and transitions have been observed between narrow dark cells with slender nuclei, rich in chromatin and light cells with rounded nuclei. An extensive contact between

penetrating nerve fibers and all types of cells brings about further difficulties in judging whether a cell has a gustatory or supporting function.

In the following part the intention is to give an account of the epithelial element of the taste buds by first describing the dark cells. This will be followed by a description of the light ones together with cells of the transitional type with widespread degenerated cytoplasmic pictures.

The dark cells at the apical surface have a brush of microvilli which projects from a rather coarse "neck". Not all the microvilli belonging to the dark cells extend from a common "neck". Many of the villi protrude directly from the surface of the cell and sometimes they can also be solitary (Fig. 4 and 5). The microvilli are surrounded on their free surface

fibellar elements of corresponding caliber are often seen infranuclearly in the cells.

The dark cells near the taste pit contain long microtubules frequently with a curved shape. These are most often spread diffusely between the thin filaments. The cytoplasm of the dark cells has a further type of fibellar structures, namely microfilaments which appear in bundles traversing the

by a double membrane (Fig 6). It cannot be established but it seems probable that the most developed microvilli are provided with fine macromolecular surface differentiations. The villi and its neck contain particularly fine fibrillar structures arranged in a parallel way. They extend from the villi and from the "neck" in the supranuclear part of the cells (Fig 7). Whether the fibers reach even further down is not clear but

fibrillar elements of corresponding caliber are often seen infranuclearly in the cells.

The dark cells near the taste pit contain long microtubules frequently with a curved shape. These are most often spread diffusely between the thin filaments. The cytoplasm of the dark cells has a further type of fibrillar structures, namely microfilaments which appear in bundles traversing the

Fig 9 Detail from fig 8. The dark cells contain numerous osmophilic granules. Centriole (Ce) Multivesiculated body (arrow) Electron microscopy 12,000 x.

From the lower part the centrioles project cross-striated rootlets toward the center of the cell. It is impossible to determine how deep these rootlets extend into the taste bud. The filaments extending from the microvilli often run in a direction opposite the centriole.

Rather densely packed mitochondria of varying size with a round to oval form occur plentifully in the cytoplasm of the dark cells. The cell contains a moderately richly developed rough endoplasmic reticulum and some multivesiculated bodies.

Adjacent cells, dark as well as light, stand in contact with one another through desmosomes, which occur rather sparsely and are mainly found in the upper region of the taste buds. Plasma membranes to adjacent cells are

Fig 8 Part of the apical half of a taste bud. The attachments between the cells are very complex. Numerous vacuoles are seen in the light cell (L) and only very few in the dark one. Bundles of filaments extend downward from the villi to the apical part of the cell. Even centrally filaments (arrow) are seen. A fine structure indicated by A. Electron microscopy 3,000 x.

cytoplasm (Fig 8 and 9). Close to the nucleus, these microfilaments are more densely arranged (Fig. 10). They chiefly appear in the supranuclear region but can often be found in the infranuclear area.

In the apical part near the taste pit the dark cell cytoplasm contains many homogeneous osmophilic granules varying in size (Fig 4 and 5). These granules appear chiefly in the supranuclear region but can be found even in the basal part of the cell.

The centrioles with their characteristic appearance are outlined as a homogeneous dense substance around a lighter center (Fig 11 and 9). They are situated quite near the upper margin of the cells, in the region between the nucleus and the pore and often at right angles to the axis of the villi.

Fig 9 Detail from fig. 6. The dark cells contain numerous ornithophilic granules. Centriole (Cc) Multi-vesiculated body (arrow) Electron microscopy 12,500 x.

From the lower part, the centrioles project cross-striated rootlets toward the center of the cell. It is impossible to determine how deep these rootlets extend into the taste bud. The filaments extending from the microvilli often run in a direction opposite the centriole.

Rather densely packed mitochondria of varying size with a round to oval form occur plentifully in the cytoplasm of the dark cells. The cell contains a moderately richly developed rough endoplasmic reticulum and some multi-vesiculated bodies.

Adjacent cells, dark as well as light, stand in contact with one another through desmosomes, which occur rather sparsely and are mainly found in the upper region of the taste buds. Plasma membranes to adjacent cells are

Fig 10. Nucleus (Nu) and the supranuclear region of a light cell in a taste bud. The cytoplasm contains bundles of filaments arranged more densely close to the nucleus. Many mitochondria (M) also are seen. Likewise the cytoplasm contains special vesicles with a darker central part. Nerve indicated by N. Electron microscopy 13,500 x

also connected to one another by complicated infoldings (Fig 11) which give a considerable increase to the cell surface. These infoldings are most pronounced in the upper region of the cells.

The light cells are also provided with microvilli on their apical surface. It seems as if these villi are less developed than those which belong to the dark cells (Fig 4). The villi often extend directly from the cell surface and a "neck" corresponding to that on the dark cells is missing. The microvilli in the light cells are also membraned and have a fine fibrillar inner structure which continues down into the cells.

The endoplasmic reticulum of the light cells is as a rule different from that in the dark cells (Fig. 4 and 8). The cytoplasm contains a large number of vacuoles and a few osmophilic granules of up to 0.5μ in size. Corresponding inner structure is often observed in the endoplasmic reticulum in taste bud cells after nerve transection to a considerably greater extent than before. Whether the presence of vacuoles and osmophilic granules in taste buds of

cells. Whether this is caused by technical problems cannot yet be decided. There should of course be some centrioles, even in these cells.

Other cell forms

Among the cell forms which cannot be classified as light and dark cells it is possible to distinguish in the main 2 categories. One of these has a nucleus with a chromatin density and a form and also an endoplasmic reticulum with a shape which compares closely to that of the dark cells. The cell has microvilli of varying length and number generally the villi extend from a neck shaped structure. Filaments and microtubuli occur but are not so regularly shaped. These cells have granules of stellar appearance to the dark cells and sometimes vacuoles also. Mitochondria and a dense mat of ribosomes accompany this cell variant. As a rule there are distinct centrioles in the supranuclear portion of the cell.

The other cell type has an appearance most like the light cell and it seems to be a further development of this type. The cytoplasm here gives the impression of being in a degenerative stage. This cell form which is found centrally in the taste bud is characterized chiefly by its rich supply of vacuoles of a definite dimension in the cytoplasm. In general microfilaments and mitochondria appear very sparsely. Both kinds of cells are in complex connection with the cells and the nerve structures.

Nerves

When investigating a specimen fixed in osmic acid and stained with paraphenylenediamine solution in light and phase contrast microscopy no

Fig. 13. Nerve fiber (N) close to termination to a dark cell. The dark cell nucleus indicated by N. Junctional complex (arrow). Electron microscopy 13 500

detailed information of the distribution of the intragemmal nerve structures and its relation to the cells is revealed. With this staining the nerves appear as light, round to oval formations between the cells. In the upper half of the taste bud they occur sparsely but it is possible to find a solitary nerve close to the taste pit. The lower half and especially the region of the nerve entrance in the taste bud, on the contrary is provided with a large number of nerve elements. The intragemmal nerves are unmyelinated, while those which are below the taste buds and deeper subepithelially are myelinated. The myelin sheath appears as a dark round ring around the axon and in this fixing and staining, it is easily distinguishable (Fig. 12)

In electron microscopy it is possible to study the ultrastructure of the nerves and the contact with the cells. In some cases, however it can be very difficult to differentiate the cells of the taste buds from those of the nerve structures. This applies particularly to those nerves situated in the proximity of the pores. Both structures are provided with membranes but

Fig. 14 Nerve ending (NE) sparsely granulated in contact with a cell. The cell contains many granules similar to synaptic vesicles just at the contact zone. Electron microscopy 38,000 x

the nerves are devoid of ribosomes. The nerves divide in their intrageminal course repeatedly and end in club-like swellings, or boutons.

The intrageminal nerves are of varying calibers and contain neurotubuli, which in specimens sectioned longitudinally have a nearly parallel course. In addition the nerves contain a few rather densely packed mitochondria (Fig 13).

In this study typical contacts of a synaptic nature have been observed between the different cells and the nerve endings. Within other sensory organs which have been studied by the research group most frequently large numbers of synaptic vesicles and granules appear. The rabbit's taste buds contain however only sparse numbers of synapses, but for these regions they have typical vesicles and granules.

The nerve endings are, as pointed out earlier club-like formations and seem from a morphological viewpoint the same as in other sensory regions like the ear or the eye to be of 2 different kinds. One of these has only a few

Fig. 15 From the basal part of two adjacent taste buds close to the nerve entrance a richly granulated neuron (NE) can be seen. It contains typical synaptic vesicles. Other nerves (N), mitochondria and multivesiculated bodies (arrows) are also visible. Electron microscopy 20 000 \times .

synaptic vesicles often with a diameter around 500–600 Å. While the presynaptic side, i.e. the sensory cell side, generally contains special synaptic organelles. Such granular presynaptic differentiations are found as "synaptic bars" (Smith and Sjöstrand, 1961; Spoendlin and Gacek, 1963). The other type of nerve ending is richly provided with synaptic vesicles and appears to be of presynaptic type. This would indicate a centrifugal conductivity in this type of nerve ending (Fig. 14 and 15).

On some occasions in this investigation contact has been observed between different types of nerve fibers indicating neuro-neuronal contacts. As in synaptic areas, these regions have a rather opaque appearance.

In this connection a further observation must be pointed out. On a number of occasions in the taste buds of the normal material, nerve structures have been observed very near to the taste pit. It has not been possible to see any characteristic synaptic structures in the contact zone between the nerve and the surrounding cell.

Fig 14 Nerve ending (NE) sparsely granulated in contact with a cell. The cell contains many granules similar to synaptic vesicles just at the contact zone. Electron microscopy 30,000 x

The rabbit's taste buds contain however only sparse numbers of synapses but for these regions they have typical vesicles and granules.

The nerve endings are as pointed out earlier club-like formations and seem from a morphological viewpoint the same as in other sensory regions like the ear or the eye, to be of 2 different kinds. One of these has only a few

Fig. 17 Nerves immediately below the base of a taste bud with myelinated and unmyelinated fibers. The myelin is distinctly lamellated. Not the outer (black arrow) and inner (white arrow) mesaxons. Schwann cell nuclei (SC). Electron microscopy 20,000 x.

AZ-staining

In this type of staining, not only the nerve structures appear but also the cell elements. The staining of the cells varies however. It seems as if those cells designated "light" are stained first. They appear as bulky formations with large, round nuclei (Fig. 20) which are a little lighter than the cell in general. Those cells which are called dark are stained more irregularly and not so distinctly (Fig. 21). Both types of cells extend from the base of the taste bud to the taste pit where they continue into microvilli.

In the study of the nerve structures, thick sections (15–20 μ) have been prepared but in spite of this it has not been possible to follow the course of the nerve complexes from the deeper area lying in the papillae among mus-

Fig 16 Part of a cross sectioned nerve below the fast bulb. This nerve has been stained by the Mallot technique. This impregnation has given a considerable density to the epineurium (E) and to the myelinated nerves (My) while the unmyelinated nerves are surrounded by Schwann cell (SC) cytoplasm only. NZ staining Mallot modified zinc iodine method. Electron microscopy 10 000 x.

As pointed out above the nerves running subepithelially are partly myelinated partly unmyelinated and of varying calibers (Fig 16). In the core of the papillae between the glandular structures and muscles, the nerves form large bundles. In electron microscopy the myelin lamellae appear very clear. Their numbers can be counted and their course followed from the outer to the inner mesaxon (Fig 17).

The unmyelinated nerves are situated close to or completely enclosed in Schwann cell (Fig 18). The axon is in this way surrounded by the double membrane from the latter.

Ganglionic cells with myelinated and unmyelinated nerves have on some occasions been observed in the subepithelial tissue (Fig 19).

Fig. 17. Nerve immediately below the base of taste bud with myelinated and unmyelinated fibers. The myelin is distinctly lamellated. Note the outer (black arrow) and inner (white arrow) membranes. Schwann cell nucleus (SC). Electron microscopy 20,000 \times .

NZ-staining

In this type of staining, not only the nerve structures appear but also the cell elements. The staining of the cells varies however. It seems as if those cells designated "light" are stained first. They appear as bulky formations with large, round nuclei (Fig. 20) which are a little lighter than the cell in general. Those cells which are called "dark" are stained more irregularly and not so distinctly (Fig. 21). Both types of cells extend from the base of the taste bud to the taste pit where they continue into microvilli.

In the study of the nerve structures, thick sections (15–20 μ) have been prepared but in spite of this it has not been possible to follow the course of the nerve complexes from the deeper area lying in the papillae among mus-

les and glandular structures to the most superficial subepithelial regions under the taste buds. There is always a rich nerve plexus running just under the epithelium along the furrows (Fig. 22). From this plexus a large number of branches occur almost at right angles to the surface. They appear not only in the region where the taste buds are situated, but also at the base of the furrows (Fig. 23). These nerves bend near the surface of the epithelium and run parallel with it. Whether these fibers terminate as "free nerve endings" has not been possible to decide in this study. In the region beneath the taste buds a nerve plexus is situated and from it nerve fibers run partially intragemmal and partially inter- and perigemmal. The nerves running outside the taste buds divide repeatedly and reach the surface of the epithelium in the furrows. Bead like swellings often occur on these nerve fibers (Fig. 22). In their course intragemmal nerve fibers also divide between the cells and a number of these nerves reach the region just under or in the taste pit.

b. The structure after nerve transection

The rabbits were sacrificed at varying intervals after transection of the glossopharyngeal nerve, as shown in table 5

Table 5 The number of rabbits and their survival time after transection of the glossopharyngeal nerve.

Survival time in days	1	2	3	4	5	6	7	10	14	30	60	180	270
Number	2	2	5	5	2	2	7	3	2	2	3	1	2

Control animal. In order to exclude the possibility that the surgery caused disturbances in the continuity of the glossopharyngeal nerve 1 animal was killed 7 days after the operation, when only the nerve was dissected out. The taste buds at the foliate papillae showed no structural changes nor did the subepithelially coursing nerves.

Macroscopic findings

Before killing the rabbits, the region with the foliate papillae was inspected via the operation microscope and the operated and unoperated sides were compared. Animals which were examined within 30 days after transection of the glossopharyngeal nerve showed no certain observable changes. 1 animal, however with a survival time of 10 days had an ulcer centrally in the papilla on the operated side and there the furrows and ridges were missing. After 30 days survival the papilla on the operated side seemed paler than on the unoperated, but the normal surface structure was preserved.

Microscopic findings

After transection of the glossopharyngeal nerve, structural changes occurred in the taste buds on the ipsilateral papillae and in the subepithelial nerve structures. The process, which was progressing, was studied by light, phase contrast and electron microscopy. As soon as 24 hours after the nerve transection there were easily visible changes, not only in the cells of the taste buds but also in the nerves running subepithelially. There are often difficulties in following the course of events in detail but in the following paragraphs, the main features of the process will be described. In studying the changes of the structures on the operated side, comparison has always taken place with the unoperated and the normal side.

The number and size of the taste buds was unchanged in the first 2 days after transection. The light cells which normally contain a few osmophilic granules, had an abundance of them in the cytoplasm. The granules increased in size and gradually clumped together. These granules were well

Fig 21 The same vesicular structures as seen in fig 10. A nerve (N) containing some granules, resembling synaptic vesicles are also seen. Electron microscopy 21 000 x

Special cytoplasmic structures in taste bud cells

On several occasions we have observed large numbers of intracytoplasmic granules in taste bud cells and even in their nuclei. These inclusions have a varying diameter (Fig 24). Each granule has a denser center and a distinct outer membrane. There are several regions indicating that the granules are more numerous close to the nerve endings than in the rest of the cells. This could indicate a connection of synaptic importance. However, these granules are considerably larger than ordinary dense core synaptic vesicles and it is quite possible that they have a totally different significance. Thus we have discussed if they could have some relation to viruses. Virus infections in the taste buds of human beings have been discussed recently by Blatt and Freeman (1968).

Fig. 27 The same specimen as in fig. 26 but here the nucleus is partly visible. The nuclear (N) membrane is diffuse but the membrane of the cell (arrow) is still distinctly visible. Electron microscopy 22,500 x.

demarcated but irregularly shaped. In some parts they contained a filamentous whirl-like inner structure, and in others they had a homogeneous appearance. The cytoplasm also contained a large number of vacuoles and gave the impression of a coarse spider's web. The fibrillary structures, both of tubular and microfilamentous character were still intact. The mitochondria were in this stage not so densely packed. The cell and nuclear membranes were intact but the nucleus had already at this stage of degeneration an irregularity in structure and the chromatin showed a tendency to clotting. The cytoplasm in the dark cells now contained a few vacuoles and the granules normally occurring in the dark cells, had increased

Fig 25 Taste buds from an animal sacrificed 3 days after transection of the glossopharyngeal nerve. The size of the taste buds and the numbers of cells is unchanged in comparison with the normal side. The eosinophilic granules appearing under normal conditions have increased in size and number. Phase contrast microscopy 800 x

Fig 26. Part of taste bud from an animal sacrificed 1 day after transection of the glossopharyngeal nerve. A an indication of degeneration, the cytoplasm contains both vacuoles and vesicles of various size. Electron microscopy 20 000 x

times appeared in normal taste buds (Fig. 26 and 27). Only a few not so densely packed mitochondria appeared (Fig. 28). The microvilli seemed to be intact. The dark cells showed no additional obvious changes on the third day compared with the second day (Fig. 29).

The size and number of the cells in the taste buds had so far been unchanged compared with those of the normal side, but between the 4th and 5th day after transection of the nerve the taste buds were more slender and had sometimes a somewhat irregular shape. The pore still remained, but all the cells did not reach it. The microvilli cannot be distinctly distinguished. This change in their outline was dependent upon the fact that

Fig. 23. Central part of a taste bud from an animal sacrificed 3 days after transection of the glossopharyngeal nerve. The nuclear membranes of both light and dark cells are not smooth any longer. Possible degeneration of some mitochondria (arrows). Electron microscopy 8500 x.

in size and were to be found uniformly in the cytoplasm. The pore with the microvilli were unchanged.

The structural changes which had occurred were most obvious in the light, most peripherally situated cells. As time proceeded after the transection of the nerve more changes appeared however also in centrally situated light cells. Between the 2nd and 3rd day after the transection there were pronounced changes of the same appearance as those just described in all light cells and in the majority of the dark cells (Fig. 25). The osmophilic granules had however increased in size likewise the vacuoles. The latter occurring in the light cells were of similar appearance to those which some-

Fig. 32. Part of taste bud from animal sacrificed 4 days after transection of the glossopharyngeal nerve. As in Fig. 29 the cytoplasm contains product of degeneration but here they have clumped and formed inhomogeneous structures (arrow). Electron microscopy 17,500 \times .

the number of cells, both light and dark, he reduced but also that they diminished in size (Fig. 30 and 31). The remaining light cells were populated by osmophilic granules and also vacuoles. The nucleus had shrunk and was often pressed like a half moon against the cell membrane by the large osmophilic clumps (Fig. 32). The cell limits cannot be followed and it was difficult to differentiate light from dark cells. The most obvious feature concerning the dark cells was that the osmophilic particles were not of the same size and the vacuoles were considerably smaller. In the

Fig. 30. Taste buds from an animal sacrificed 4 days after transection of the glossopharyngeal nerve. The reduction of the number of cells has started and the osmophilic granules are clumped. The vacuoles appear especially around the light cell's nuclei. Phase contrast microscopy. 830 x.

Fig. 34. Taste buds from an animal sacrificed 5 days after transection of the glossopharyngeal nerve. The left taste bud is more slender than the normal one. The taste pit is still intact. Intragemmally there occur eosinophilic granules of varying size. The membranes of the cells and nuclei are partly disappeared. Phase contrast microscopy 680 x.

Fig. 35. Taste bud from an animal sacrificed 6 days after transection of the glossopharyngeal nerve. The taste bud is in a stage of degeneration and there are few cells left. Phase contrast microscopy 790 x.

Fig 33 Degeneration products in a light cell from a taste bud 5 days after transection of the glossopharyngeal nerve. The osmiophilic clump has in some parts a filamentous whirl like structure and in others a more homogeneous appearance. Electron microscopy $\times 2,000$ x

dark cells as in the light ones a considerable reduction of the cytoplasm had occurred as well a pyknotic degeneration of the nucleus. The chromatin clustered in the peripheral region most often (Fig 33).

The degeneration which took place after nerve transection was, as pointed out earlier progressive. From the 5th to the 6th day an obvious reduction in the number of taste buds occurred and the remainder diminished considerably in size. The remaining cells were in a state of degeneration of the same appearance as described after the fourth to fifth day (Fig 34 and 35).

After the 7th to the 8th day however there were no taste bud like structures in the epithelium on the papillae. There were a few remnants of irregular osmiophilic clumps, vacuoles and some single cells noted on the

Fig. 38. Taste bud from animal sacrificed 8 days after transection of the glossopharyngeal nerve. The remainder of a taste bud is only some single cells, vacuoles and granules. Phase contrast microscopy 1100 x.

Fig. 39. Central part of foliate papilla with ridges and furrows from an animal sacrificed 14 days after transection of the glossopharyngeal nerve. A taste bud can be seen and the epithelium along the furrows is uninterrupted and stratified. Phase contrast microscopy 100 x.

Fig 36

sile of the taste buds. The taste pore was defective and the epithellum in the pores assumed a more and more regular stratification (Fig 36 and 37)

Between the 8th and 14th day after the transection of the glossopharyngeal nerve it was possible to find only a few remainders of degenerated products of taste buds in the epithellum (Fig 38)

The foliate papillae on rabbits which survived more than 14 days after the transection had a total loss of taste buds. The epithellum on the ridges was regularly stratified and without defects (Fig 39). The even cupola shaped top of the ridges had except in 2 rabbits been preserved. These 2 animals had a survival time of 30 and 90 days. The most superficial part of the epithelial layers seemed to disappear in these cases. For the rest

Fig. 41

Cross and longitudinally sectioned nerves in the core of a filio papilla from an animal sacrificed 3 days after transection of the glossopharyngeal nerve. The myelin sheaths are in different stages of degeneration and the myelin is clumped. The axons are still present. Phase contrast microscopy. Fig. 40 730 x, fig. 41 610 x.

Fig. 42. Cross-sectioned nerve (arrows) in the subepithelial region in a foliate papilla from an animal sacrificed 8 months after transection of the glossopharyngeal nerve. No myelin can be seen but the presence of connective tissue is remarkable. Phase contrast microscopy 690 x.

the normal form of the foliate papillae was preserved. The furrows, however, became shallower when the animals survived longer and the epithelium against the furrows had also thinned out.

The nerve structures situated subepithelially also passed through a degeneration process after transection of the glossopharyngeal nerve. This process was visible after 1 to 2 days. The normal myelin pattern disappeared. The round dark rings of myelin around the axon took on an ellipsoidal shape, and became irregular or clumped together. In nerves longitudinally sectioned this clumping of the myelin was more easily observed. The myelin diminished after a certain time passed following nerve transection (Fig. 40 and 41). After 4 to 8 days it was possible to see only some myelin clumps in both longitudinally and cross sectioned specimens. The unmyelinated nerve fibers also took on a diffuse appearance. 10 to 14 days after nerve transection the myelin had disappeared. The outer structure of the nerves appeared but it was impossible to distinguish the individual fibers. The nerves were filled with connective tissue (Fig. 42). This picture appeared in all the specimens where the animal had survived for more than 30 days.

c. The structure after nerve suture

In this section of the investigation 19 rabbits have been used. The time of survival and the number in each group is shown in table 6.

Table 6 The number of rabbits and their survival time after suture of the glossopharyngeal nerve

Survival time in days	10	14	30	90	180	210	240	270
Number	2	2	1	1	3	4	5	1

Macroscopic findings

The region with the foliate papillae on the rabbit's tongue was inspected via the operation microscope and the operated and unoperated side were compared. The normal surface structure was preserved. The furrows, however, seemed to be shallower on the operated than on the unoperated side in animals killed more than 30 days after suture of the glossopharyngeal nerve. The papillae on these rabbits were paler on the operated than on the unoperated side.

Microscopic findings

In rabbits which are killed 10 days after suture of the glossopharyngeal nerve the foliate papillae have no taste buds of normal appearance. There is a reduction in the total amount of taste buds and the remaining ones are in a degenerative stage and have the same appearance as those described in the chapter on nerve transection. The subepithelial nerve structures have been changed and the regularity in the pattern of the myelinated nerves is lost. The myelin remains only as solitary, irregularly shaped clumps.

14 days after suture of the glossopharyngeal nerve the papillae are completely devoid of taste buds and the epithellium present is regularly formed. Myelinated nerves are also completely absent in the subepithelial tissue. 1, 3 and 6 months after the suture there are still no taste bud like structures visible on the foliate papillae. As after only nerve transection the ridges and furrows are well preserved. The furrows are however considerably shallower here than on the papillae of normal animals.

The animals whose foliate papillae are examined between 7 and 9 months after suture of the glossopharyngeal nerve show indications of activity within the epithellium. The regular pattern is disturbed. The subepithelial tissue projects in the epithelial layer on the lateral side of the ridges. These projections of stroma are composed of besides connective tissue and nerve structures, also cell collections which in the beginning are arranged in irregular formations (Fig. 43). These collections of cells are considered to be presumptive taste buds.

Fig. 43

Fig. 44.

Beginning of regeneration of the taste buds in f late papilla between 6 and 7 months after suture of the glossopharyngeal nerve in both these figures. Please contrast microscopy. Fig. 43 930 \times ; fig. 44 1100 \times .

The presumptive taste buds are connected to the subepithelial tissue by a basement membrane and superficially by squamous cells. No taste pore can be seen. The cells inside the presumptive taste buds are elongated, and contain a nucleus. In the beginning the structures are not differently stained. With increased passage of time after the suture of the nerve, more cells in the epithelial layer take the shape of a taste bud-like structure (Fig. 44). The epithelial surface is at last pierced and structures of definite

c. The structure after nerve suture

In this section of the investigation 19 rabbits have been used. The time of survival and the number in each group is shown in table 6.

Table 6 The number of rabbits and their survival time after suture of the glossopharyngeal nerve

Survival time in days	10	14	30	90	180	210	240	270
Number	2	2	1	1	3	4	5	1

Macroscopic findings

The region with the foliate papillae on the rabbit's tongue was inspected via the operation microscope and the operated and unoperated side were compared. The normal surface structure was preserved. The furrows, however, seemed to be shallower on the operated than on the unoperated side in animals killed more than 30 days after suture of the glossopharyngeal nerve. The papillae on these rabbits were paler on the operated than on the unoperated side.

Microscopic findings

In rabbits which are killed 10 days after suture of the glossopharyngeal nerve the foliate papillae have no taste buds of normal appearance. There is a reduction in the total amount of taste buds and the remaining ones are in a degenerative stage and have the same appearance as those described in the chapter on nerve transection. The subepithelial nerve structures have been changed and the regularity in the pattern of the myelinated nerves is lost. The myelin remains only as solitary irregularly shaped clumps.

14 days after suture of the glossopharyngeal nerve the papillae are completely devoid of taste buds and the epithelium present is regularly formed. Myelinated nerves are also completely absent in the subepithelial tissue. 1, 3 and 6 months after the suture there are still no taste bud like structures visible on the foliate papillae. As after only nerve transection the ridges and furrows are well preserved. The furrows are however considerably shallower here than on the papillae of normal animals.

The animals whose foliate papillae are examined between 7 and 9 months after suture of the glossopharyngeal nerve show indications of activity within the epithelium: the regular pattern is disturbed. The subepithelial tissue projects in the epithelial layer on the lateral side of the ridges. These projections of stroma are composed of besides connective tissue and nerve structures, also cell collections which in the beginning are arranged in irregular formations (Fig. 43). These collections of cells are considered to be presumptive taste buds.

Fig. 46.

Fig. 47

Fig 45 Regenerating taste buds from a foliate papilla 8 months after suture of the glossopharyngeal nerve. A taste pit is developed and is wider than a normal one. Phase contrast microscopy 1160 x.

taste bud appearance are present. With the break through on the surface of the epithelium the pore has been formed. The pores are wide and clumpy and most often there are several within the same taste bud. Microvilli are at first not seen as a rule but in some pores they are seen at the apical ends of the taste bud cells. The cells seem to reach from the basement membrane to the pore. The nuclei are elongated and more darkly stained than the cytoplasm and situated in the lower two thirds of the cell (Fig 45).

Parallel with this development of taste bud like structures the myelinated nerves begin to regenerate. The myelin in the nerves however is not so regular and densely arranged as normally but occurs in irregular formations in the nerve bundles (Fig 46 and 47).

This development of taste bud like structures does not occur uniformly in the whole papilla. In certain areas there is a total loss of taste buds of nearly normal appearance. Rabbits with a survival time of over 9 months after nerve suture have fully developed taste buds. The numbers vary however within the ridges some ridges completely lack a trace of taste buds.

In all cases where suture of the glossopharyngeal nerve is carried out the nerve has been dissected out and the site of the suture examined when the rabbits are killed. It is thereby established that in all cases the 2 ends of the sectioned nerve have grown together to form a new nerve.

microscopy Murray and Murray (1967) and Farhman (1965 a) show that those cells they describe as supporting cells are furnished with microvilli in their apical region also. These cells always reach up to the taste pit.

In the present investigation it is shown that all cells within the taste buds, reach to the taste pit and there they end in microvilli of varying length and number. Villi belonging to the dark cells appear to be more highly differentiated and of larger dimensions than those of the other cells. The occurrence of microvilli causes the cells to have a considerably larger contact surface in the pore. This without doubt, is of functional importance. If the microvilli also are furnished with fine macro-molecular surface differentiations this would increase the contact surface still further. But as pointed out earlier it is not possible to decide whether or not these structures occur on the most differentiated villi. The possibility of an artifact through a shrinking process in the preparation and fixing can not be excluded. Fawcett (1965) describes similar structures on the intestinal epithelium and says that they form a part of the cell membrane and take part in the resorptive process of the cell membrane in the intestine. Theoretically it can be the same in the taste buds.

There is no certain information concerning the significance which the various cytoplasmic organelles in the taste cells have from a functional viewpoint. The osmophilic granules, which are of the same appearance as the osmophilic substance in the taste pore have as a rule been observed in the dark cells (Iriki, 1960; de Lorenzo, 1958, 1963 a; Nemetschek-Gansler and Ferner 1964; Farhman 1965 a; Murray and Murray 1967) but also appear in the light cells. They are however considerably smaller and not so numerous in the light cells (de Lorenzo, 1958, 1963 a; Iriki, 1960). The granules, which most frequently occur in the border zone against the taste pit, have been considered to be a sign that the cells possess a gustatory function and should thus be the result of a resorptive process. Murray and Murray (1967) put forward the view that granules are produced in the dark cells and the basic substance in the taste pore is a product thereof.

Osmophilic granules, as shown in this study are found in the dark cells and chiefly in the supranuclear portion of the cytoplasm just under the taste pit. The light cells also contain these granules, but as a rule, they are of considerably greater dimensions.

Iriki (1960) and de Lorenzo (1958, 1960, 1963 a) are the only electron microscopists, who have observed vacuoles in both cell forms. The author also has found vacuoles in both cell types.

Kolmer (1910) describes fibrillary structures in certain cells and considers this to denote a supporting function in the cell. In earlier electron microscopic studies (Trujillo-Cenóz, 1957; Farhman, 1965 a; Murray and Murray 1967) as in the present investigation, besides these fibrillary structures, also tubula and others of microfilamentous character have been observed. In the author's investigation, many of the tubular structures have

IV DISCUSSION AND CONCLUSIONS

a The normal structure

The structure of the taste buds has as appears from the literature review been the object of extensive light microscopic studies. During the last decade electron microscopy has also been applied. Even in the earliest studies on the structure of the taste buds it is possible to distinguish different types of cells. This distinction is based mainly on the position within the taste buds, the form, size and the relationship to the nervous components.

There is unanimous agreement that the taste buds contain sensory cells. The occurrence of supporting cells, on the other hand, has been argued. The majority of authors consider as appears from the literature review that this cell form does exist.

It is pointed out in the description of the structure of the taste buds that there are small structural differences between the taste bud cells. This is the reason why there are difficulties in classifying the cells. The majority of earlier authors divide the cells according to their function, i.e. into sensory cells and supporting cells, in spite of the lack of physiological documentation.

The author considers as more adequate to apply a descriptive division based on the general appearance of the nucleus and cytoplasm of the cells occurring in the rabbits' taste buds. The main types of cells in both light microscopy and electron microscopy have been designated as light and dark cells. Several authors have previously divided the cells from the same point of view but at the same time classified them from a physiological viewpoint. The dark cells, as a rule, have been regarded as sensory cells and the light ones as supporting cells (de Lorenzo 1958, 1960, 1963; Iriki 1960; Nemetschek-Casler and Ferner 1964). In the Murray group there is a certain doubtfulness about the division. In 1961 both the light and the dark cells were regarded as gustatory but in 1967 the light ones were considered to be sensory cells. Farbman (1965 a) has described 4 cell types where type I corresponds to the dark and type II to the light cells. Murray and Murray (1967) like the author have not found any cell corresponding to Farbman's cells designated as peripheral and basal. In all probability the peripheral cells are the counterpart to the perigemmal cells.

The taste buds have a specific function and the cells have an ultrastructure different from that of the surrounding cells. The taste pore is the only region where the taste bud stands in contact with the surface of the tongue through microvilli. The taste pit contains an osmophilic substance which is considered to be of importance for the stimulation of taste. The earlier idea was that only sensory cells have contact with the pores. With electron

microscopy Murray and Murray (1967) and Farbman (1965 a) show that those cells they describe as supporting cells are furnished with microvilli in their apical region also. These cells always reach up to the taste pit.

In the present investigation it is shown that all cells within the taste buds, reach to the taste pit and there they end in microvilli of varying length and number. Villi belonging to the dark cells appear to be more highly differentiated and of larger dimensions than those of the other cells. The occurrence of microvilli causes the cells to have a considerably larger contact surface in the pore. This without doubt is of functional importance. If the microvilli also are furnished with fine macro-molecular surface differentiations this would increase the contact surface still further. But as pointed out earlier it is not possible to decide whether or not these structures occur on the most differentiated villi. The possibility of an artifact through a shrinking process in the preparation and fixing can not be excluded. Fawcett (1965) describes similar structures on the intestinal epithelium and says that they form a part of the cell membrane and take part in the resorptive process of the cell membrane in the intestine. Theoretically it can be the same in the taste buds.

There is no certain information concerning the significance which the various cytoplasmic organelles in the taste cells have from a functional viewpoint. The oenophilic granules, which are of the same appearance as the oenophilic substance in the taste pore have as a rule been observed in the dark cells (Iriki, 1960 de Lorenzo, 1958, 1963 a Nemetschek-Gansler and Ferner 1964 Farbman, 1965 a Murray and Murray 1967) but also appear in the light cells. They are however considerably smaller and not so numerous in the light cells (de Lorenzo, 1958, 1963 a Iriki, 1960). The granules, which most frequently occur in the border zone against the taste pit, have been considered to be a sign that the cells possess a gustatory function and should thus be the result of a resorptive process. Murray and Murray (1967) put forward the view that granules are produced in the dark cells and the basic substance in the taste pore is a product thereof.

Oenophilic granules, as shown in this study are found in the dark cells and chiefly in the supranuclear portion of the cytoplasm just under the taste pit. The light cells also contain these granules, but as a rule they are of considerably greater dimensions.

Iriki (1960) and de Lorenzo (1958, 1960 1963 a) are the only electron microscopists, who have observed vacuoles in both cell forms. The author also has found vacuoles in both cell types.

Kolmer (1910) describes fibrillary structures in certain cells and considers this to denote a supporting function in the cell. In earlier electron microscopic studies (Trujillo-Cendz, 1957 Farbman 1965 a Murray and Murray 1967) as in the present investigation besides these fibrillary structures, also tubular and others of microfilamentous character have been observed. In the author's investigation many of the tubular structures have

a pronounced curved form. It should be pointed out that microfilaments also occur in the infranuclear part of the both cell types.

From the discussion it is evident that there are differences of opinion regarding the structure of the taste buds and the interpretation of the findings. An explanation of this can be that various animals have been investigated, namely monkeys (Murray and Murray 1960), rats (Gray and Watkins, 1965; Farhman 1965 a) and rabbits (Engström and Rytznér 1956 a, b; Trujillo-Cenóz, 1957; de Lorenzo, 1958; 1960; 1963 a; Iriki, 1960; Nemetschek-Gansler and Ferner 1964; Murray and Murray 1967). But perhaps, as pointed out by many authors, it might be that fixation is highly variable in quality. In addition there are great individual variations in the taste buds in the same animal species.

The cells in this study designated light and dark have greater similarities than differences in structure. Both types of cells are furnished with microvilli of similar inner structure. The relation to nervous components is the same and the greater part of the cytoplasmic organelles are of the same pattern. That which chiefly differentiates the cells is the varying density of the chromatin in the nuclei, the formation of the endoplasmic reticulum and the distribution of osmophilic particles. The cells which are designated otherwise have, as is clear from the earlier account, pronounced similarities with one or the other of the principal forms.

Through experimental investigations (Beidler et al. 1960; Beidler 1961; 1963; Beidler and Smallman 1965; de Lorenzo, 1963 b; Robbins, 1967) it has been proved that a continuous degeneration and renewal of cells occurs in the taste buds. In the perigemmal epithelial layer a continuous cell division takes place and the newly formed cells invade the center of the taste buds, where after a time they degenerate.

Murray and Murray (1967) state "It might be argued that only one cell type exists since there seems to be a pattern of continuous transition from perigemmal cell through various stages to cell degeneration."

In the present work mitoses have not been seen and it has not been possible to decide if perigemmal cells are transformed to gemmal and there pass through various stages. The fact that the cells in the taste buds do not show such great structural differences can be an indication that there is one cell form only which passes through various stages of development. It seems as if the cell degeneration and cell breakdown especially affects the light cell form. This can indicate that this cell is either a late stage in the further development of the dark cell and represents an aging form or that it represents a separate and more vulnerable cell.

As a summary it can be pointed out that on the basis of observations made of the structure of the cells in the taste buds of the rabbit in spite of structural differences it cannot be definitely decided whether both sensory cells and supporting cells occur. It is most probable however that the cells during their life-cycle pass through different stages. The results

of this study are mainly in favor of the view that in taste buds there is only one cell form which may have a different appearance and this cell must have a gustatory function.

The Nerves

Sometimes it is difficult to differentiate nerve structures from sensory cells, especially in the upper regions of the taste buds. The intragemmal nerves divide repeatedly in their course and end in a club-like, enlarged nerve ending. In earlier studies on warm-blooded animals it has not been possible to decide whether both afferent and efferent nerve endings exist. De Lorenzo (1963 a) has discussed this question chiefly against the background of showing different calibers in the nerve fibers and he has separated both the inner structure and various ways of contact with the receptors.

Desgranges (1966) in his studies of the taste buds on *Ameiurus*, an amphibian found nerves and nerve endings which are designated as afferent and efferent. These nerve structures, as is clear from the present investigation, appear richly in the basal region of the taste buds. Typical nerve endings are few but it is possible to distinguish 2 forms. One form is only sparsely furnished with vesicles and granules while the other is more richly supplied with these structures. In comparison with nerve endings in other sensory organs such as the cochlea and vestibularis, the former which is most commonly occurring, corresponds to afferent and the latter to efferent nerve endings. Both types of nerve endings stand in synaptic contact with either light or dark cells. Gray and Watkins (1965) have primarily studied the synaptic regions in the taste buds and they point out that these are not wholly typical or of the same appearance as those in other sense organs. Synapses with both vesicles and granules have been observed in the present investigation, but they are extremely sparse and this constitutes a phenomenon difficult to explain. In other sense organs and in regions with synaptic contact the synaptic regions usually appear distinct. For many years, at the same laboratory great interest has been devoted to the study of synapses between sensory cells and nerves. There has also been great interest devoted to the study of synapses in the central nervous system with exactly the same method as in e.g. the inner ear or medulla oblongata studies, where characteristic synaptic regions appear in great numbers (Engström, 1969).

Synapses should be found between receptor cells and nerve endings, but Farbman (1965 a) and Murray and Murray (1967) however have found synaptic contacts also in cells which they regard as supporting cells. In the present study synapses have been observed between all cell types and nerve endings. This observation can support the assumption that the intragemmal cells constitute one cell form in various stages of development and all with gustatory function.

This study confirms the statement of Gray and Watkins (1965) that

a pronounced curved form. It should be pointed out that microfilaments also occur in the infranuclear part of the both cell types.

From the discussion it is evident that there are differences of opinion regarding the structure of the taste buds and the interpretation of the findings. An explanation of this can be that various animals have been investigated namely monkeys (Murray and Murray 1960) rats (Gray and Watkins, 1955; Farbman 1965 a) and rabbits (Engström and Rytznér 1956 a b Trujillo-Cenoz, 1957 de Lorenzo 1958 1960 1963 a Irkl 1960 Nemetschek-Gansler and Ferner 1964 Murray and Murray 1967). But perhaps as pointed out by many authors it might be that fixation is highly variable in quality. In addition there are great individual variations in the taste buds in the same animal species.

The cells in this study designated light and dark have greater similarities than differences in structure. Both types of cells are furnished with microvilli of similar inner structure. The relation to nervous components is the same and the greater part of the cytoplasmic organelles are of the same pattern. That which chiefly differentiates the cells is the varying density of the chromatin in the nuclei the formation of the endoplasmic reticulum and the distribution of osmophilic particles. The cells which are designated otherwise have as is clear from the earlier account pronounced similarities with one or the other of the principal forms.

Through experimental investigations (Beidler et al., 1960 Beidler 1961 1963 Beidler and Smallman 1965 de Lorenzo, 1963 b Robbins 1967) it has been proved that a continuous degeneration and renewal of cells occurs in the taste buds. In the perigemmal epithelial layer a continuous cell division takes place and the newly formed cells invade the center of the taste buds where after a time they degenerate.

Murray and Murray (1967) state "It might be argued that only one cell type exists since there seems to be a pattern of continuous transition from perigemmal cell through various stages to cell degeneration."

In the present work mitoses have not been seen and it has not been possible to decide if perigemmal cells are transformed to gemmal and there pass through various stages. The fact that the cells in the taste buds do not show such great structural differences can be an indication that there is one cell form only which passes through various stages of development. It seems as if the cell degeneration and cell breakdown especially affects the light cell form. This can indicate that this cell is either a late stage in the further development of the dark cell and represents an aging form or that it represents a separate and more vulnerable cell.

As a summary it can be pointed out that on the basis of observations made of the structure of the cells in the taste buds of the rabbit in spite of structural differences it cannot be definitely decided whether both sensory cells and supporting cells occur. It is most probable however that the cells during their life-cycle pass through different stages. The results

The changes are best seen in the peripherally situated cells on the taste buds but they successively progress to the central portion. Parallely there follows a structural degeneration also in the nerves running subepithelially

The foliate papillae from rabbits which are examined 1 3 6 and 9 months after nerve transection show a total loss of taste buds. Our studies have never indicated that extensive spontaneous degeneration of the taste buds happens with intact nerve function.

Von Vintschgau (1880) and Meyer (1896) consider that the disappearance of the taste buds after transection of the corresponding nerve takes place through de-differentiation or metamorphic transformation of the supporting cells in the taste buds but, not the sensory cells. Ranvier (1888) Olmsted (1921) Whiteside (1927) and Guth (1937) are of the opinion that a degenerative process takes place. In earlier works there are, however no detailed histological investigations of the course of events, when taste buds disappear after nerve transection. Robbins (1967) also discussed the possibility of inhibition of the mitotic activity and that the differentiation to mature cells is stopped. The above mentioned factors, plus the possibility of local circulatory disturbances and sensitivity disturbances with increased erosion of the mucous membrane will be discussed

Investigations (Beidler et al., 1960 Beidler 1961 1963 de Lorenzo, 1963 b Beidler and Smallman, 1965 Robbins, 1967) have shown that there is high mitotic activity in the perigemmal cells and that the newly formed cells wander into the center of the taste buds. In addition there is a constant breaking down of older cells taking place in the taste buds. The number of the intragemmal cells and the shape of the taste buds under normal conditions is unchanged. This is apart from the physiological age involution of the sense organ.

Robbins (1967) points out that the mitotic activity ceases after nerve transection. From this study it is evident that a rapid reduction of the number of cells in the taste buds occurs. This should indicate a decrease or reduction in the mitotic activity with reduced new cell formation. Another possibility is that the nerve transection causes an increased cell breakdown. Under these conditions, however the total disappearance of the taste buds should not have occurred. It is most probable therefore that the mitotic activity does not go on in the normal way. With diminished or wholly inhibited mitotic activity there will be no addition of cells in the taste buds and accordingly no differentiation.

The cells in the taste buds are highly collected in the bulb during the time of the process, even if at times it looks as they project into the surrounding tissue. Artifacts, through incorrect sectioning cannot be completely excluded. This collection of the cells in groups discourages the idea of a de-differentiation or metamorphic transformation of the cells during the process.

In this investigation there has not been any study of the circulation in

synaptic contacts only exist between the receptor cells and the terminal dilatation of the axons

Kolmer (1927) like the author has observed ganglion cells in the subepithelial tissue. The possibility that these ganglion cells belong to the glands in the subepithelial tissue cannot however be excluded

AZ staining

According to Maillet (1963) osmium tetroxid stains the structures which contain lipoproteins such as nerve endings and preganglionic and post ganglionic fibers in the autonomic system and motor end plates.

Through the staining of the taste buds it has not been possible to differentiate the nerve endings into afferent and efferent. Besides nerve structures and cells the AZ staining of the taste buds has also brought to view a structure of special appearance which stretches from the nerve plexus under the taste bud to the pore. The nature of this structure cannot be decided.

b The structure after nerve transection

In most studies as appears from the literature review where taste nerves have been divided morphological changes in the taste buds are seen after some time. These changes finally cause the total disappearance of the taste buds. It is however not clear from the earlier investigations how the degeneration occurs in detail. The process at least in warm blooded animals starts within 1 to 5 days after the nerve transection and is considered to be finished with total disappearance of the taste buds within 1 to 3 weeks.

Normally the taste buds of rabbits never have shown degenerative changes of an appearance and extent that have been observed after transection of the glossopharyngeal nerve. It can therefore be stated that the changes which occur in the taste buds after the transection are dependent on the broken nerve continuity.

The process through which the taste buds degenerate and disappear starts within 24 hours after the nerve transection and is visible in both light phase contrast and electron microscope. The process is progressive and after 14 days the taste buds have completely disappeared. Both light and dark cells are affected by the changes. The light cells get an increased vacuolizing within the beginning small vacuoles and these gradually increase and become confluent. Osmiophilic granules and lysosomes are also formed in the cytoplasm. The dark cells get an increase of osmiophilic granules and vacuoles appear in the cytoplasm. Nuclear and cell limits are blotted out and finally there remains an unhomogeneous dark structure a product of degeneration which soon disappears. A combined reduction in the size of the taste buds and the number of the cells within each taste bud occurs from the 4th day. The changes are most easily followed in the light cells.

c. The structure after nerve suture

The occurrence of taste buds in the studies of regeneration of gustatory nerves has been considered to be proof that a reinnervation has taken place.

From the review of the literature appears that suturing of a gustatory nerve after transection results in development of taste buds after some time. The circumstances are the same after the anastomosis of a central portion of a gustatory nerve with a non-gustatory. The results, however, diverge when the central part of a non-gustatory nerve and the distal part of a gustatory nerve are sutured.

Earlier studies, as appears from literature review have shown that a degeneration of the taste buds takes place immediately after sectioning and suturing of gustatory nerves. After a varying interval of time taste bud-like formations are seen.

In the present study the glossopharyngeal nerve in rabbits has been sutured after transection. The foliate papillae are examined after various time intervals with regard to the occurrence of taste buds. As in only transection of the glossopharyngeal nerve, rabbits which are killed between 2 weeks and 6 months after suturing the nerve show a total lack of taste buds on the foliate papillae. 7 to 8 months after the operation the epithelium contains areas with structures which, in comparison with taste buds during development in fetal stage, show a remarkable resemblance (Farbman, 1965 b; Bradley and Stern, 1967).

It is possible to distinguish 2 steps in the course of events after suture of the glossopharyngeal nerve. In the first step the taste buds degenerate at the same time as changes occur in the nerves running subepithelially. In the second step the taste buds are reformed and the nerves regain their normal appearance.

In judging the results of this investigation there are a number of factors which can affect the course of events and therefore will be discussed in the following.

Circulatory disturbances. At the operation, the glossopharyngeal nerve is dissected free in the region where the division and suturing will take place. The operation is carried out with great care but injury to the fine capillary network with accompanying oedema in the nerve cannot be avoided. The nerve however is situated in soft tissues and has the possibility of expanding in its surroundings and will not be compressed. Serious disturbances to the function will not arise. Hence it is less likely that circulatory disturbances should influence the course of events and the result of the investigation. There would not have been total disappearance of taste buds either if there had been circulatory disturbances.

Innervation. Through anatomical studies (Chapt. B. I. a.) it is known that the taste buds on the foliate papillae on the rabbit's tongue are homolaterally innervated. The author's investigation concerning the taste buds after

the mucous membrane, either under normal or pathological conditions. In the examination no necrosis have been observed in the taste papillae except for in 1 case where there was a large necrotic ulcer. Without doubt a profound transformation occurs in the taste buds after transection of the nerve but if a local circulatory disturbance contributes is not clear in that case. The histological picture would have been different and there would have been vast necrosis.

In examination of the taste papillae there has been no indication of erosion of the surface epithelium except in the case just mentioned.

All types of cells in the taste buds after nerve transection have changes of a morphological nature with degeneration products of lysosomal character in the cytoplasm and redistribution of the chromatin in the nucleus. Phagocytosing cells are very seldom seen in the taste buds. It is therefore less likely that the degeneration products are transported away through phagocytosis. Lysosomes normally contain a series of hydrolytic enzymes, which on the death of the cells are liberated and contribute to the dissolution of the cell (Norén 1908). Gahan (1965) has shown that the permeability of the lysosomes membrane is changed in connection with operative intervention on rat liver. Hypothetically it can be assumed that changes in the permeability of the membrane of the lysosomes can also arise after nerve transection and this creates possibilities for the enzymes to affect the cytoplasm. Further studies can definitely solve this problem.

Olmsted (1920 a) May (1925) and Torrey (1934 1936) have in their studies on the effects of transection the taste nerves on cat fish discussed the possibility of a neurohumoral factor to maintain the connection between nerve and taste cell. The process by which the taste buds in these cold blooded animals disappears, starts initially after some days with a free interval and ends within a few days. The authors consider that the nerve normally contains this substance and that the amount in the peripheral stump would have been used up before the breakdown starts. Whiteside (1927) and Guth (1957) discuss this hypothesis and point out that the course of events in warm blooded animals is quite different from that in cold-blooded ones. As pointed out above the degenerative process is of a progressive nature with immediate effect after the transection of the nerve. Thus there is nothing that supports any agreement with the hypothesis of a neurohumoral factor.

Summarizing, it can be pointed out that after transection of the glossopharyngeal nerve on rabbits structural changes arise in the taste buds cells on the foliate papillae. These degenerations finally lead to a total disappearance of taste cells. These changes are in all probability the result of an inhibited mitotic activity and cell degeneration. The fact that the cells within the taste buds vanish after nerve transection can be a support for the opinion stated in the summary of the normal structure that in the taste buds there is only one cell type, which passes through various stages.

c. The structure after nerve suture

The occurrence of taste buds in the studies of regeneration of gustatory nerves has been considered to be proof that a reinnervation has taken place.

From the review of the literature appears that suturing of a gustatory nerve after transection results in development of taste buds after some time. The circumstances are the same after the anastomosis of a central portion of a gustatory nerve with a non-gustatory. The results, however, diverge when the central part of a non-gustatory nerve and the distal part of a gustatory nerve are sutured.

Earlier studies, as appears from literature review have shown that a degeneration of the taste buds takes place immediately after sectioning and suturing of gustatory nerves. After a varying interval of time taste bud-like formations are seen.

In the present study the glossopharyngeal nerve in rabbits has been sutured after transection. The foliate papillae are examined after various time intervals with regard to the occurrence of taste buds. As in only transection of the glossopharyngeal nerve, rabbits which are killed between 2 weeks and 6 months after suturing the nerve, show a total lack of taste buds on the foliate papillae. 7 to 8 months after the operation the epithelium contains areas with structures which, in comparison with taste buds during development in fetal stage, show a remarkable resemblance (Farbman, 1965 b Bradley and Stern, 1967).

It is possible to distinguish 2 steps in the course of events after suture of the glossopharyngeal nerve. In the first step the taste buds degenerate at the same time as changes occur in the nerves running subepithellally. In the second step the taste buds are reformed and the nerves regain their normal appearance.

In judging the results of this investigation there are a number of factors which can affect the course of events and therefore will be discussed in the following.

Circulatory disturbances. At the operation, the glossopharyngeal nerve is dissected free in the region where the division and suturing will take place. The operation is carried out with great care but injury to the fine capillary network with accompanying oedema in the nerve cannot be avoided. The nerve however is situated in soft tissues and has the possibility of expanding in its surroundings and will not be compressed. Serious disturbances to the function will not arise. Hence it is less likely that circulatory disturbances should influence the course of events and the result of the investigation. There would not have been total disappearance of taste buds either if there had been circulatory disturbances.

Innervation. Through anatomical studies (Chapt. B. I. a.) it is known that the taste buds on the foliate papillae on the rabbit's tongue are homolaterally innervated. The author's investigation concerning the taste buds after

the mucous membrane either under normal or pathological conditions. In the examination no necrosis have been observed in the taste papillae except for in 1 case, where there was a large necrotic ulcer. Without doubt a profound transformation occurs in the taste buds after transection of the nerve but if a local circulatory disturbance contributes is not clear in that case. The histological picture would have been different and there would have been vast necrosis.

In examination of the taste papillae there has been no indication of erosion of the surface epithelium except in the case just mentioned.

All types of cells in the taste buds after nerve transection have changes of a morphological nature with degeneration products of lysosomal character in the cytoplasm and redistribution of the chromatin in the nucleus. Phagocytosing cells are very seldom seen in the taste buds. It is therefore less likely that the degeneration products are transported away through phagocytosis. Lysosomes normally contain a series of hydrolytic enzymes, which on the death of the cells are liberated and contribute to the dissolution of the cell (Norden 1968). Gabon (1965) has shown that the permeability of the lysosomes membrane is changed in connection with operative intervention on rat liver. Hypothetically it can be assumed that changes in the permeability of the membrane of the lysosomes can also arise after nerve transection and this creates possibilities for the enzymes to affect the cytoplasm. Further studies can definitely solve this problem.

Olmsted (1920 a) May (1925) and Torrey (1934 1936) have in their studies on the effects of transection the taste nerves on cat fish discussed the possibility of a neurohumoral factor to maintain the connection between nerve and taste cell. The process by which the taste buds in these cold blooded animals disappears starts initially after some days with a free interval and ends within a few days. The authors consider that the nerve normally contains this substance and that the amount in the peripheral stump would have been used up before the breakdown starts. Whiteside (1927) and Guth (1957) discuss this hypothesis and point out that the course of events in warm-blooded animals is quite different from that in cold blooded ones. As pointed out above the degenerative process is of a progressive nature with immediate effect after the transection of the nerve. Thus there is nothing that supports any agreement with the hypothesis of a neurohumoral factor.

Summarizing it can be pointed out that after transection of the glossopharyngeal nerve on rabbits structural changes arise in the taste buds cells on the foliate papillae. These degenerations finally lead to a total disappearance of taste cells. These changes are in all probability the result of an inhibited mitotic activity and cell degeneration. The fact that the cells within the taste buds vanish after nerve transection can be a support for the opinion stated in the summary of the normal structure that in the taste buds there is only one cell type which passes through various stages.

C. CAN CHORDA TYMPANI BE REPAIRED?

From the present clinical study in Chapt. A IV It is evident that injuries to the chorda tympani with attending functional disturbances are far from unusual. This study only discusses these problems in connection with surgery for otosclerosis. However a large number of other operations are also performed in the middle ear either for hearing improvement or for cleaning. Temporal bone fractures sometimes cause damage to the chorda tympani.

From the experimental investigation in Chapt. B III. c. it is evident that a suture of the glossopharyngeal nerve in rabbits can give reinnervation and induce the development of taste buds on the foliate papillae. It is also supposed that the reinnervation is a direct result of the suturing of the nerve. The question arises Is it possible in man to suture the chorda tympani and get recovery of the loss of taste in that part of the tongue which is affected by the injury? So far as is known no such nerve sutures have as yet been carried out on the chorda tympani. In the following there will be a discussion of the various possibilities of restoring the continuity of the chorda tympani.

The chorda tympani can be accidentally or voluntarily injured with an interruption of the continuity in its course through the middle ear or in the bone in the posterior wall of the auditory canal. At radical mastoidectomy the nerve very often can be dissected free. The chorda tympani is under these conditions more easily accessible and it should be possible to restore the continuity. The experiences from these operations can then be applied to other conditions. It should be possible, although difficult, to restore the continuity of the chorda tympani when it is interrupted in the free course through the middle ear.

Accidental interruption of the continuity of the chorda tympani can arise in the entrance of the nerve into the middle ear at the level of the posterior wall of the auditory canal. In certain cases it should be possible to dissect the proximal portion of the nerve free from the surrounding bone and get a small chorda-stump before it joins the facial nerve. Even in these cases it should be possible to restore the continuity of the chorda tympani.

However if the chorda tympani lesion is in the anterior portion of the

transection of the glossopharyngeal nerve unilaterally has shown a complete lack of taste buds ipsilaterally after 9 months. Thus, there is no indication that the contralaterally coursing glossopharyngeal nerve should maintain or induce the formation of taste buds.

Spontaneous regeneration Through the nerve transection experiment partly here and partly in the studies of others it is shown that spontaneous development of the taste buds does not occur. Nerve structures are seen to play an important role.

Relation nerve-receptor Embryological and experimental investigations on mammals have shown that taste buds are dependent for their existence of intact nerve function. Contrary to these are the experiments in urodele where tissue is transplanted from the tongue containing taste buds to the orbit, liver, side-line organs or tail. After a degenerative phase, regeneration of taste buds is proved (Stone, 1933; Mintz and Stone, 1934; Wright 1951, 1955, 1958). The authors consider that it is not possible for the transplanted tissue to have contact with gustatory nerves. The final conclusion is that taste buds can develop without the presence of nervous components. Poritsky and Singer (1963) showed however by means of nerve staining technique that there are regenerated nerve structures from orbital nerves in the transplanted tongue tissue when taste buds start to develop. Special nerve staining has not been carried out in the above reported investigation. It is very likely that the authors had to revise their categorical conclusion if the nerve staining technique had been used.

Robbins (1967) shows that after transection of the lingual nerve bilaterally but without suturing on a frog, reinnervation and development of taste buds arise through sprouting of fibers from the facial and glossopharyngeal nerves. These experiments should support the idea that taste buds in cold blooded animals at least can develop without being induced by nerves carrying only gustatory nerve fibers. The above discussed investigations of Boeke (1917) and Olmsted and Pinger (1936) can possibly also support the notion that the same conditions prevail in warm-blooded animals.

Against the background of the results in this investigation and the unmistakable resemblance between those structures observed in this study after reinnervation and taste buds under development during the fetal period (Farbman 1965 b; Bradley and Stern 1967) it must be supposed that a regeneration of taste buds has occurred. Whether the regenerated taste buds possess functional properties cannot be decided on the basis of the present morphological study.

C. CAN CHORDA TYMPANI BE REPAIRED?

From the present clinical study in Chapt. A. IV It is evident that injuries to the chorda tympani with attending functional disturbances are far from unusual. This study only discusses these problems in connection with surgery for otosclerosis. However a large number of other operations are also performed in the middle ear either for hearing improvement or for cleaning. Temporal bone fractures sometimes cause damage to the chorda tympani.

From the experimental investigation in Chapt. B. III c. It is evident that a suture of the glossopharyngeal nerve in rabbits can give reinnervation and induce the development of taste buds on the foliate papillae. It is also supposed that the reinnervation is a direct result of the suturing of the nerve. The question arises: Is it possible in man to suture the chorda tympani and get recovery of the loss of taste in that part of the tongue which is affected by the injury? So far as is known, no such nerve sutures have as yet been carried out on the chorda tympani. In the following there will be a discussion of the various possibilities of restoring the continuity of the chorda tympani.

The chorda tympani can be accidentally or voluntarily injured with an interruption of the continuity in its course through the middle ear or in the bone in the posterior wall of the auditory canal. At radical mastoidectomy the nerve very often can be dissected free. The chorda tympani is under these conditions more easily accessible and it should be possible to restore the continuity. The experiences from these operations can then be applied to other conditions. It should be possible, although difficult, to restore the continuity of the chorda tympani when it is interrupted in the free course through the middle ear.

Accidental interruption of the continuity of the chorda tympani can arise in the entrance of the nerve into the middle ear at the level of the posterior wall of the auditory canal. In certain cases it should be possible to dissect the proximal portion of the nerve free from the surrounding bone and get a little chorda-stump before it joins the facial nerve. Even in these cases it should be possible to restore the continuity of the chorda tympani.

However if the chorda tympani lesion is in the anterior portion of the

transection of the glossopharyngeal nerve unilaterally has shown a complete lack of taste buds ipsilaterally after 9 months. Thus, there is no indication that the contralaterally coursing glossopharyngeal nerve should maintain or induce the formation of taste buds.

Spontaneous regeneration Through the nerve transection experiment partly here and partly in the studies of others it is shown that spontaneous development of the taste buds does not occur. Nerve structures are seen to play an important role.

Poritsky and Singer (1963) showed however by means of nerve staining technique that there are regenerated nerve structures from orbital nerves in the transplanted tongue tissue when taste buds start to develop. Special nerve staining has not been carried out in the above reported investigation. It is very likely that the authors had to revise their categorical conclusion if the nerve staining technique had been used.

Robbins (1967) shows that after transection of the lingual nerve bilaterally but without suturing on a frog reinnervation and development of taste buds arise through sprouting of fibers from the facial and glossopharyngeal nerves. These experiments should support the idea that taste buds in cold blooded animals at least can develop without being induced by nerves carrying only gustatory nerve fibers. The above discussed investigations of Boeke (1917) and Olmsted and Pinger (1936) can possibly also support the notion that the same conditions prevail in warm blooded animals.

Against the background of the results in this investigation and the unmistakable resemblance between those structures observed in this study after reinnervation and taste buds under development during the fetal period (Farbman 1965 b; Bradley and Stern 1967) it must be supposed that a regeneration of taste buds has occurred. Whether the regenerated taste buds possess functional properties cannot be decided on the basis of the present morphological study.

GENERAL DISCUSSION

Every year many patients go through different types of middle ear operations. The chorda tympani can then be lesioned accidentally or voluntarily. Temporary or permanent disturbances in the taste function of the anterior parts of the tongue may then arise.

As shown from the clinical part of this investigation patients with both preserved and divided chorda tympani at surgery for otosclerosis perceive taste impairments. In most earlier studies (table 1 and 2) the taste function has been recorded subjectively. As is pointed out in Chapt. A. V the patients' sensation of taste impairment is influenced by several factors. The result of only subjective recordings must be valued critically. In this study the electrical taste test according to Hrarup's electrogustometry and tests with solutions according to Börnsteln have been used. These tests are objective but factors of subjective or psychophysical nature are included. Hence they cannot be considered as quite satisfactory. In practical work the methods, however, are applicable.

The chorda tympani contains taste fibers in the anterior two thirds of the tongue and dividing the nerve gives total loss of taste. No regeneration of the nerve after transection has been established. The chorda tympani has been divided in about 10 % during the surgery for otosclerosis. In comparison with earlier presented materials, the frequency is low (table 3). The course of the chorda tympani in the middle ear and its relation to the other structures reveals that it must be divided in some cases. The patients then perceive taste impairments. Even if the chorda tympani at the operation is preserved many patients experience permanent taste impairment.

This study comprises only the functional disturbances of taste after surgery for otosclerosis. The chorda tympani contains however among other components, secretory fibers to salivary glands. Injuries to the nerve also can give disturbances in the salivary secretion (Wilberg, 1969).

The results in this investigation speak in favor of the opinion that the chorda tympani, whenever it is possible without jeopardizing the operation for otosclerosis, shall be preserved. Today bilateral stapes surgery is usual. This fact strengthens the opinion that the chorda tympani shall be preserved at the operation.

One of the important questions behind this study has been to discover if nature of the divided chorda tympani can give regeneration of the nerve and induce regeneration of taste buds. To answer this question it was considered necessary to perform experimental investigations.

In order to interpret the results, the normal structure of the taste bud must be known as well as the morphological changes after nerve transection.

middle ear the possibility of regaining the continuity is considered to be non-existent.

Special difficulties are afforded in the technical performance of nerve suture or other methods which will be discussed in the following. In modern equipment for microsurgery of the ear there is a comprehensive instrumentarium which can be adapted and used for the intended operation.

By manufacturing extremely small fine needles it should be possible to restore the continuity in the chorda tympani with normal suture technique. The suture material chosen must fulfill the highest demands of tissue compatibility not only regarding the nerve itself but also regarding the other structures in the middle ear.

The plasma clot method (Tarlov et al. 1943; Tarlov and Brooklyn 1944; Tarlov and Boernstein 1948) is conceivable for use in certain cases of adaptation of the divided nerve ends but the method has its limitations. This has been pointed out by among others, Edsberg (1964) in the following way: "the junction however in practice proved to be so weak that the plasma clot had to be combined with epineurial suture." Edsberg (1964) too, has discussed the following methods for joining transected nerves: Union of nerve ends by tubular splicing, Epineurial sleeve and Venous sheath fat seal. He has pointed out that these methods are often technically difficult to carry out and traumatic for the nerve. If these methods are not applicable on free running peripheral nerves, it is inconceivable to apply them to the nerve in question which besides being inaccessible is also very thin. Finally the possibility of using "clips" of resorbent or permanent material to join the nerve ends should be investigated.

From the discussion it is evident that it is possible in certain cases by special methods to restore the continuity of the chorda tympani.

In this study the electrical taste test according to Krarup's electrogustometry and tests with solutions according to Bornstein have been used. These tests are objective but factors of subjective or psychophysical nature are included. Hence they cannot be considered as quite satisfactory. In practical work the methods, however, are applicable.

The chorda tympani contains taste fibers in the anterior two thirds of the tongue and dividing the nerve gives total loss of taste. No regeneration of the nerve after transection has been established. The chorda tympani has been divided in about 100 % during the surgery for otosclerosis. In comparison with earlier presented materials, the frequency is low (table 3). The course of the chorda tympani in the middle ear and its relation to the other structures reveals that it must be divided in some cases. The patients then perceive taste impairments. Even if the chorda tympani at the operation is preserved many patients experience permanent taste impairment.

This study comprises only the functional disturbances of taste after surgery for otosclerosis. The chorda tympani contains however among other components, secretory fibers to salivary glands. Injuries to the nerve also can give disturbances in the salivary secretion (Wiberg, 1969).

The results in this investigation speak in favor of the opinion that the chorda tympani whenever it is possible without jeopardizing the operation for otosclerosis, shall be preserved. Today bilateral stapes surgery is usual. This fact strengthens the opinion that the chorda tympani shall be preserved at the operation.

One of the important questions behind this study has been to discover if suture of the divided chorda tympani can give regeneration of the nerve and induce regeneration of taste buds. To answer this question it was considered necessary to perform experimental investigations.

In order to interpret the results, the normal structure of the taste bud must be known as well as the morphological changes after nerve transection.

Studies about the structure of the taste buds under normal conditions are extensive. The earliest investigations were performed by using light microscopy. In the last decade however electron microscopy has been used. The interpretation of the morphology in respect to various cell forms, the relation to nerve structures and the pattern of innervation are different.

The foliate papillae on rabbits have been studied. As is pointed out by others, difficulties in getting suitable and applicable fixing technique exist. Veronal buffered 1.5 % osmic acid solution and in some cases glutaraldehyde or Mallet's modified zinc iodine solution (NZ staining) have been used and it has been possible to analyze the structures in both light phase contrast and electron microscopy.

Normally the taste buds contain cells which in various fixings and stainings appear differently. This has resulted in various authors describing several cell forms. As is seen from the discussion in Chapt. B IV a the most accepted opinion is that taste buds contain supporting and sensory cells. Difficulties exist in classifying the cells into different groups from a physiological point of view on the basis of structural differences. In view of the appearance of the cells they have been termed light and dark cells. Normally the cells in the taste buds have on their surface microvilli reaching into the taste pit. Generally the light cells contain villi not so well developed as that on the dark cells and the light cells seem to be older than the dark ones. Both cell types contain osmophilic granules and vacuoles. The light cells however have numerous vacuoles and a few granules, while the dark cells have a few vacuoles and many granules. The other organelles have the same appearance in both cells. Synaptic contacts have also been observed between the nerve endings and both cell types. The nerve endings seem to be afferent and efferent. Some of the cells in the taste buds have an uncharacteristic appearance and cannot be assigned to the two main groups. It is impossible to state if they are intermediary forms.

The findings in this investigation are in agreement with other results. But earlier electron microscopic authors have always tried to classify the cells from a physiological aspect and then attempted to find out as many differences as possible in the cells.

It may be stated on the basis of the results in this investigation that it seems plausible that the cells have the same basic structure but pass different stages. The light cell seems to be the oldest and the dark the youngest.

Earlier studies, when the taste nerves have been divided have shown that the taste buds degenerate and after some time disappear completely. The course of events however has not been studied in detail.

In this investigation the glossopharyngeal nerve has been exposed on the rabbits just below the entrance and close to the base of the skull. This nerve has been chosen because it is easy to reach. As early as 1 to 2 days after transection of the nerve, the cells in the taste buds show degenerative changes. The process proceeds and after 14 days there is a total loss of taste.

buds. In the beginning, the vacuoles increase in size and number and the granules increase in both cell forms. The osmophilic granules, especially in the dark cells increase in size. Some of the granules seem to be lysosomes. The number of cells is reduced and the size of the taste buds diminishes with time. As is pointed out in the discussion in Chapt. B. IV, changes which are observed in the taste buds after transection of the nerve are dependent upon a blocked mitotic activity and resulting in a degenerative process. The subepithelial coursing nerves also show degeneration.

Further confirmation that the cells in the taste buds normally pass through different stages during life span is shown after studying the structure of the taste buds after transection of the nerve. It can be established that all cells in the taste buds contain degenerative changes which with time lead to total disappearance of the taste buds. The fact that the same changes occur in all cells may support the interpretation that all cells have the same origin. The cells may be considered to be gustatory. The taste bud may be interpreted as a structure with specific function situated in the epithelium of the tongue papillae.

No spontaneous regeneration of the taste buds occurs after transection of the nerve which contains gustatory fibers in the corresponding region. Studies on the taste buds after partial denervation of the glossopharyngeal nerve have not been performed. The continuity of the nerve must be restored.

Only a few earlier studies exist where the taste nerves after transection have been sutured. The histological documentation, however is defective. In the last part of the present investigation the glossopharyngeal nerve was sutured after the transection to restore the continuity. A degenerative process of the same type as seen after transecting only the nerve is seen. Also there is total disappearance of the taste buds occurring after about 2 weeks. No taste buds can be seen until about 6 to 7 months. 7 to 8 months after the suture of the nerve, at the foliate papillae, structures can be seen that form the presumptive taste buds. From a morphological point of view a great many taste buds of the same appearance as seen normally can be observed. The subepithelial coursing nerves also show regeneration with new formations of myelin. Whether these regenerated taste buds possess functional qualities cannot be decided by this study. Physiological studies in the future may solve these problems.

It can be stressed that suture of the glossopharyngeal nerve in rabbits gives a regeneration of the nerve which induces development of taste buds at the foliate papillae. This does not necessarily imply that suturing of the chorda tympani should result in regeneration of taste buds. The circumstances can be otherwise with respect to the chorda tympani as well as human beings. It can, however as is pointed out in Part C, be a reason for restoring the continuity of the chorda tympani in a number of cases and with special instruments where it has been divided at middle ear surgery.

Studies about the structure of the taste buds under normal conditions are extensive. The earliest investigations were performed by using light microscopy. In the last decade, however, electron microscopy has been used. The interpretation of the morphology in respect to various cell forms, the relation to nerve structures and the pattern of innervation are different.

The foliate papillae on rabbits have been studied. As is pointed out by others, difficulties in getting suitable and applicable fixing technique exist. Veronal buffered 1.5 % osmic acid solution and in some cases glutaraldehyde or Maillet's modified zinc iodine solution (NZ staining) have been used and it has been possible to analyze the structures in both light phase contrast and electron microscopy.

Normally the taste buds contain cells which in various fixings and stainings appear differently. This has resulted in various authors describing several cell forms. As is seen from the discussion in Chapt. B IV, the most accepted opinion is that taste buds contain supporting and sensory cells. Difficulties exist in classifying the cells into different groups from a physiological point of view on the basis of structural differences. In view of the appearance of the cells they have been termed light and dark cells. Normally the cells in the taste buds have on their surface, microvilli reaching into the taste pit. Generally the light cells contain villi not so well developed as that on the dark cells and the light cells seem to be older than the dark ones. Both cell types contain osmophilic granules and vacuoles. The light cells however have numerous vacuoles and a few granules, while the dark cells have a few vacuoles and many granules. The other organelles have the same appearance in both cells. Synaptic contacts have also been observed between the nerve endings and both cell types. The nerve endings seem to be afferent and efferent. Some of the cells in the taste buds have an uncharacteristic appearance and cannot be assigned to the two main groups. It is impossible to state if they are intermediary forms.

The findings in this investigation are in agreement with other results. But earlier electron microscopic authors have always tried to classify the cells from a physiological aspect and then attempted to find out as many differences as possible in the cells.

It may be stated on the basis of the results in this investigation that it seems plausible that the cells have the same basic structure but pass different stages. The light cell seems to be the oldest and the dark the youngest.

Earlier studies when the taste nerves have been divided have shown that the taste buds degenerate and after some time disappear completely. The course of events however has not been studied in detail.

In this investigation the glossopharyngeal nerve has been exposed on the rabbits just below the entrance and close to the base of the skull. This nerve has been chosen because it is easy to reach. As early as 1 to 2 days after transection of the nerve, the cells in the taste buds show degenerative changes. The process proceeds and after 14 days there is a total loss of taste.

buds. In the beginning, the vacuoles increase in size and number and the granules increase in both cell forms. The osmiophilic granules, especially in the dark cells increase in size. Some of the granules seem to be lysosomes. The number of cells is reduced and the size of the taste buds diminishes with time. As is pointed out in the discussion in Chapt. B IV b changes which are observed in the taste buds after transection of the nerve are dependent upon a blocked mitotic activity and resulting in a degenerative process. The subepithelial coursing nerves also show degeneration.

Further confirmation that the cells in the taste buds normally pass through different stages during life span is shown after studying the structure of the taste buds after transection of the nerve. It can be established that all cells in the taste buds contain degenerative changes which, with time, lead to total disappearance of the taste buds. The fact that the same changes occur in all cells may support the interpretation that all cells have the same origin. The cells may be considered to be gustatory. The taste bud may be interpreted as a structure with specific function situated in the epithelium of the tongue papillae.

No spontaneous regeneration of the taste buds occurs after transection of the nerve which contains gustatory fibers in the corresponding region. Studies on the taste buds after partial denervation of the glossopharyngeal nerve have not been performed. The continuity of the nerve must be restored.

Only a few earlier studies exist where the taste nerves after transection have been sutured. The histological documentation, however is defective. In the last part of the present investigation the glossopharyngeal nerve was sutured after the transection to restore the continuity. A degenerative process of the same type as seen after transecting only the nerve is seen. Also there is total disappearance of the taste buds occurring after about 2 weeks. No taste buds can be seen until about 6 to 7 months. 7 to 8 months after the suture of the nerve at the foliate papillae structures can be seen that form the presumptive taste buds. From a morphological point of view a great many taste buds of the same appearance as seen normally can be observed. The subepithelial coursing nerves also show regeneration with new formations of myelin. Whether these regenerated taste buds possess functional qualities cannot be decided by this study. Physiological studies in the future may solve these problems.

It can be stressed that suture of the glossopharyngeal nerve in rabbits gives a regeneration of the nerve which induces development of taste buds at the foliate papillae. This does not necessarily imply that suturing of the chorda tympani should result in regeneration of taste buds. The circumstances can be otherwise with respect to the chorda tympani as well as human beings. It can however as is pointed out in Part C, be a reason for restoring the continuity of the chorda tympani in a number of cases and with special instruments where it has been divided at middle ear surgery.

SUMMARY

The present investigation consists of three parts. The first part is a clinical study and gives an account of the taste function after surgery for otosclerosis. The second part is an experimental study and describes the structure of the taste buds on rabbits' foliate papillae under normal conditions, after transection of the glossopharyngeal nerve and after suture of the glossopharyngeal nerve. The third part comprises a discussion of methods to restore the continuity of the injured chorda tympani in humans.

A survey of the literature on the course and function of the chorda tympani in human is presented as well as methods to examine the taste function in clinical practice. In tabular form are the investigations about the taste of patients operated upon for otosclerosis where the chorda tympani is divided or preserved. The frequency of divided chorda tympani at stapes surgery is also reported.

In 141 patients operated upon for otosclerosis the taste function was followed for 12 months or more. In 74 of the patients the chorda tympani was divided during operation. Subjective taste impairment was registered. Objective taste tests were applied using electrical stimulation according to Hrarup and stimulation by solutions according to Hörnstein.

If the chorda tympani was preserved 8% of the patients had subjective taste impairment more than 12 months after operation. The corresponding number was 2% when the chorda tympani was divided. The objective tests showed impairment in as much as 50% of the patients if the chorda tympani was preserved and in 100% if it was divided.

From the results it can be concluded that the chorda tympani whenever it is possible without jeopardizing the stapes operation shall be preserved. The conclusion is strengthened by the fact that the number of patients undergoing bilateral stapes surgery increases every year.

In the experimental section is a survey of the literature on the normal taste sensory organ. Its development under the fetal period, the innervation, the occurrence of papillae and taste buds and the structure from a macroscopic as well as a microscopic point of view. The structure of taste buds after transection and after suture of gustatory nerves is reviewed.

Taste buds from rabbits' foliate papillae have been studied in light phase

contrast and electron microscope. The results are presented and illustrated by several photomicrographs.

Normally the cells in the taste buds have in view of their appearance been termed light and dark cells. Some of the cells however have an uncharacteristic appearance and cannot be assigned to the main groups. Synaptic contacts have been observed between the nerve endings and both cell types. The cells seem to have the same basic structures and pass through different stages. The light cell seems to be the oldest and the dark the youngest.

Transection of the glossopharyngeal nerve causes changes of a degenerative nature in all cells of the taste bud and finally total disappearance of the taste buds. This fact supports the interpretation that the cells have the same origin.

It thus can be stressed that in the taste buds of rabbits there is one cell form which passes different stages during life span. The cell may have a gustatory function. The taste bud may be interpreted as a structure with specific function situated in the epithelium of the tongue papillae.

No spontaneous regeneration of taste buds occurs after transection of the glossopharyngeal nerve. Studies on the taste buds after partial denervation of the glossopharyngeal nerve have not been performed. Suture of this nerve in rabbits gives regeneration of the nerve. The regenerated nerve induces development of structures which from a morphological point of view seem to be taste buds. It cannot be decided if these regenerated taste buds possess functional qualities.

In the last part of the present study there is a discussion of methods for restoring continuity of the injured chorda tympani. The experimental part shows that in rabbits regeneration of taste buds occurs after suture of the nerve belonging to the region. The circumstances can be otherwise in human beings. It may however in some patients be reason to try to restore the continuity of the chorda tympani when it has been divided at surgery for otosclerosis. In the future the methods will be elaborated.

SUMMARY

The present investigation consists of three parts. The first part is a clinical study and gives an account of the taste function after surgery for otosclerosis. The second part is an experimental study and describes the structure of the taste buds on rabbits foliate papillae under normal conditions after transection of the glossopharyngeal nerve and after suture of the glossopharyngeal nerve. The third part comprises a discussion of methods to restore the continuity of the injured chorda tympani in humans.

A survey of the literature on the course and function of the chorda tympani in human is presented as well as methods to examine the taste function in clinical practice. In tabular form are the investigations about the taste of patients operated upon for otosclerosis where the chorda tympani is divided or preserved. The frequency of divided chorda tympani at stapes surgery is also reported.

In 141 patients operated upon for otosclerosis the taste function was followed for 12 months or more. In 34 of the patients the chorda tympani was divided during operation. Subjective taste impairment was registered. Objective taste tests were applied using electrical stimulation according to Hrarup and stimulation by solutions according to Börnstein.

If the chorda tympani was preserved 0 % of the patients had subjective taste impairment more than 12 months after operation. The corresponding number was 2 % when the chorda tympani was divided. The objective tests showed impairment in as much as 50 % of the patients if the chorda tympani was preserved and in 100 % if it was divided.

From the results it can be concluded that the chorda tympani whenever it is possible without jeopardizing the stapes operation shall be preserved. The conclusion is strengthened by the fact that the number of patients undergoing bilateral stapes surgery increases every year.

In the experimental section is a survey of the literature on the normal taste sensory organ, its development under the fetal period, the innervation, the occurrence of papillae and taste buds and the structure from a macroscopic as well as a microscopic point of view. The structure of taste buds after transection and after suture of gustatory nerves is reviewed.

ACKNOWLEDGEMENTS

The present study has been carried out at the Departments of Otorhinolaryngology University of Göteborg and Uppsala.

I wish to express my gratitude to my chief Professor Gosta Herberts, M D head of the Department of Otorhinolaryngology Göteborg for his kind encouragement interest and stimulating criticism.

To my teacher Professor Hans Engström M D head of the Department of Otorhinolaryngology Uppsala I wish to express my deepest gratitude for stimulating discussions constructive advice and helpful supervision during the electronmicroscopic study in his laboratory

To Docent Olle Hallén M D., the Department of Otorhinolaryngology Göteborg Docent Ingmar Engberg, M D Physiological Institute, Göteborg Anton Andersson Research Engineer and Berit Engström Research Engineer I also wish to express my gratitude

My thanks are also due to my colleagues and other staff especially the secretaries at the Departments of Otorhinolaryngology

This investigation was supported in part by grants from the Faculty of Medicine, University of Göteborg and in part by the Physiological Psychology Branch, Office of Naval Research Washington D C., under contracts F61052 67 C 0090 with H Engström

PREFACE

This monograph presents extensive data on a single patient. We feel that the effort is justified by the extraordinary set of circumstances leading to the identification and evaluation of this unique hearing disorder.

The patient was a 21 year-old member of the United States Air Force. During an 8-month period from August 1967 to March 1968 he sustained two separate cerebral hemisphere infarctions: the first on the left side, the second on the right side. Damage was maximal in the temporal lobes. The first episode produced no apparent deficit in auditory sensitivity, but the second produced severe bilateral hearing loss. Thanks to the monitoring audiometry program of the Air Force both premorbid status and postmorbidity changes in auditory sensitivity were well documented.

We feel that this patient's findings are unique for two reasons: first, because he demonstrated the reality of "cortical deafness" as a clinical entity; and second, because he presented an unusual opportunity to study impairment of auditory function consequent on bilateral temporal lobe damage. Through the cooperation of the United States Air Force we were able to gather extensive psychoacoustic data during a one-week period of intensive testing. The results are detailed in succeeding chapters.

This study would not have been possible without the generous assistance of Major James Endicott, USAF, and Mr. Alan Rost, of the Audiology Section, Wilford Hall USAF Hospital, who carried out all of the initial audiometry and successfully coordinated the subsequent audiologic evaluation. Their contribution is gratefully acknowledged. We are indebted to Mr. James Thelin for his valuable assistance in the collection and analysis of data, and to Mrs. J. Ward Williams for the preparation of illustrative material.

I INTRODUCTION

The concept of cortical deafness has been the subject of some controversy considerable confusion but little information. Even the extent of the primary auditory cortex in the human has not been clearly defined. There is general agreement that the temporal lobes, and particularly the transverse temporal gyri, constitute at least a major portion of this functional unit, and that each cochlea is bilaterally represented (Crosby Humphrey and Lauer 1962) Indirect evidence obtained from animal experimentation implicates scattered regions of parietal and insular cortex as well (Pribram, Rowner and Rosenblith, 1954 Woolsey 1960) It is, therefore, not at all surprising that unilateral temporal lobe lesions do not lead to any gross auditory disorders either in animals or in man (Bunch, 1928 Mettler 1934 Penfield and Evans, 1934 Goldstein, Goodman, and King, 1936) Conventional audiometric tests, like the pure tone audiogram and routine speech discrimination tests, exhibit no significant abnormalities as the result of such lesions. Rather specialized testing techniques are required to demonstrate that such unilateral lesions indeed have any effect on auditory function. The deficits most readily demonstrable are in impairment in the ability to localize sound in the contralateral auditory field (Sanchez-Longo, Forster and Auth, 1957) and a deterioration in the discrimination of distorted, interrupted or accelerated speech in the contralateral ear (Bocca, Calero, Cavalari, and Miglioracca, 1955 Bocca, 1958 Jerger 1960 b Jerger 1964)

Conversely experimentally produced lesions of both temporal lobes in animals can produce marked diminution in hearing (Mettler 1934) In man, bilateral temporal lobe lesions are rarely produced surgically and, when produced are intentionally confined to the anterior portions, when ever possible thus sparing the transverse temporal gyri, as illustrated by the case described by Terzian and Dalle Ore (1955) In this patient, marked changes in behavior and in visual gnostic functions occurred, but no obvious auditory or aphasic disturbances were detected. Neither do auditory disturbances necessarily occur even in the face of rather marked bilateral posterior temporal lobe disease (Landau, Goldstein and Kleffner 1960) However frank hearing loss thought to be due to cerebral disease has been reported only in patients with demonstrable or presumed, naturally-occurring lesions in both posterior temporal lobes (Mott, 1907 Henschel, 1917 Bramwell, 1927 Misch, 1928 Clark and Russel, 1938 Lemoyne 1944 Lemoyne and Mahoudeau, 1950 Maspétiol, Measmy and Semelle 1959 Hansen and Rleske-Nielsen, 1963) Yet even these cases

II CASE HISTORY

First admission

The patient, a white male telephone maintenance worker was 20 years old when he was first admitted to the Wilford Hall USAF Hospital on 29 August 1967. He is left-eyed, right footed and ambidextrous, using his left hand for such tasks as writing and his right hand for eating and bowling. On the day of admission to the hospital, shortly after rising and eating breakfast he had experienced the abrupt onset of left frontal headache, numbness and paresthesias of the right hand and difficulty in the production and in the understanding of speech. He denied disturbance of consciousness, weakness, palpitations and other cardiac symptoms, recent illnesses, and the recent intake of medications.

There was no past history of rheumatic fever, other cardiac disease, thrombophlebitis and other thromboembolic diseases, migraine or significant head trauma. There was no family history of heart disease, cerebrovascular disease, migraine, hypertension or diabetes mellitus.

The patient appeared inappropriately unconcerned and smiling. Height 69 inches, Weight 134 pounds. Pulse 100 per minute. Blood pressure 100/78. General physical examination was within normal limits. Carotid pulses and peripheral pulses were full. There were no cervical or cranial bruits. Whispered voice, Schwabach, Rinne and Weber tests revealed normal hearing. However he was thought to have a mild receptive aphasia as evidenced by occasional inappropriate responses to questions and instructions. He spoke freely and spontaneously with frequent pauses, as if searching for words. He volunteered the information that he knew what he wanted to say but could not do so. Paraphasia was also evident thus, he said "knives" instead of "needles", "patches" instead of "matches", "hander" instead of "handle" and "pen" instead of "pen". Both spontaneous writing and writing from dictation exhibited word, syllable, and letter reversal and skipping. He read fluently within the limitations of his dysphasia, making no more errors than during conversational speech. There were questionable flattening of the right nasolabial fold, slight hypalgesia and hypesthesia distally in the right upper extremity and absence of abdominal reflexes on the right. Neurological examination was otherwise entirely unremarkable.

Hematocrit, hemoglobin, white blood cell count, sedimentation rate, urinalysis, blood urea nitrogen, serum creatinine, fasting blood sugar, serum cholesterol and electrocardiogram were within normal limits. X rays of the chest and skull were normal. Lumbar puncture revealed normal pressure

have not been universally accepted as being representative of cortical deafness. Thus, for example Goldstein denies the existence of even "a single convincing case study in which there is an unequivocally measured reduction in (auditory) sensitivity with a clearly demonstrable CNS lesion and no demonstrable peripheral lesion" (Di Carlo, Kendall and Goldstein 1962). Among the cited inadequacies of the published case studies are the following: (1) existence of only anecdotal information concerning premorbid auditory function (i.e., lack of premorbid audiometric studies); (2) history of tinnitus and/or vertigo not usually expected with cortical disease, or a failure to report their absence; (3) advanced age of the patient raising the possibility of presbycusis; (4) failure to report a negative family history of deafness; (5) failure to report a negative history of excessive noise exposure; (6) intake of ototoxic drugs or failure to report a negative history thereof; (7) significant head trauma or failure to report a negative history thereof; (8) presence of systemic disease that could affect eighth nerve function or inadequate data to exclude such a possibility; (9) presentation of only behavioural audiometry and failure to report results of electrophysiologic (i.e. electrodermal and/or electroencephalic) audiometry; and (10) lack of histopathologic studies of cochlea and auditory nerves at autopsy. In each of the previously reported cases, many of these objections were pertinent.

We have had the opportunity to study a young patient with deafness clearly due to cerebral disease. Since he has survived his illness, histopathologic study of cochlea and auditory nerves was not available. However, all of the other objections have been answered by the data to be presented, including premorbid audiometry. For this reason and because of the apparent rarity of this entity, the case is presented in considerable detail.

exhibiting a moderately clear area of increased uptake in the left temporal region (Fig. 2 A and 2 B) EEG ten days after admission was normal. A percutaneous left carotid arteriogram was done 13 days after admission. This exhibited nonfilling of the angular and posterior parietal branches of the left middle cerebral artery during the arterial phase and retrograde filling of these branches during the late capillary and early venous phases (Fig. 3 A and 3 B).

The patient's production and understanding of speech and his hand writing improved gradually. Two months after admission the following tests were administered: Wechsler Adult Intelligence Scale, Bender-Gestalt, Wechsler Memory Scale Form II, Minnesota Percepto-Diagnostic Test, Kahn Test of Symbol Arrangement and the Eisenson Test for Aphasia. The patient still had some discrete mild to moderate expressive and receptive aphasia. He could count, write numbers and letters, spell correctly from dictation, name objects and do arithmetic computations. The only expressive ability involved was oral reading. In this area he exhibited sound substitution, such as "rub" for "run" and "fable" for "table". It was also noted that many questions had to be repeated before the patient would respond, some distractibility and a somewhat frenzied, disorganized approach in solving visual-motor tasks were noted. Overall, however, there had not been severe deterioration. Intellectual functioning was in the average range with a verbal IQ score of 97, performance IQ 98, and full scale IQ 97. The patient himself felt that he had returned completely to normal. He was discharged from the hospital two months after admission and was able to return to his usual duties. There had been no subjective complaint or objective evidence of hearing loss throughout the period of observation. No audiometric studies were accomplished during this admission.

Second admission

The patient was readmitted to the hospital on 20 March 1968. In January 1968 he had begun noting increased nervousness and excessive sweating. Otherwise he had felt well until the day of admission. Weight loss and heat intolerance were denied.

He had retired on the night prior to admission, feeling and hearing well, and had set his alarm clock as was his custom. When he awoke the following morning, he found his alarm clock had rung 30 minutes previously and had failed to waken him. He was also immediately aware that the world about him was *strangely silent*. He could not hear the running of water from the faucet, the buzz of his electric razor or the sound of traffic on the street. When others spoke to him, he heard nothing and was able to comprehend what was being said only with great difficulty by carefully observing their lips and gestures. He experienced no headaches, tinnitus, vertigo or other symptoms referable to the ears or to the central nervous system, and he denied excessive noise exposure, the intake of ototoxic drugs, a history of otitis media or a family history of deafness.

Fig 1 Electroencephalograms. (A) On day of first admission (20 August 1967) 2.5 minutes after starting hyperventilation, exhibiting delta activity over left anterior hemisphere (B) On day of second admission (20 March 1968) prior to utilization of activation technique, exhibiting theta activity over right posterior hemisphere

and clear CSF which contained no red or white blood cells, 10 mg percent sugar and 17 mg percent protein CSF VDRI was non reactive Resting FEC was normal during hyperventilation, rhythmic delta activity occurred in brief bursts over the left hemisphere only (Fig 1 A)

Pulse and blood pressure became normal within 24 hours and remained so thereafter The neurological abnormalities disappeared in three to four days. Technetium 99m brain scan one day after admission was abnormal

was normal. Except for being loud, his speech was normal. Weight 135 pounds. Pulse 110 per minute. Blood pressure 158/70. Pulses were again full to palpation, and there were again no cervical or cranial bruits. The skin was warm and moist. The thyroid gland was diffusely enlarged to an estimated twice normal size the right lobe being larger than the left. He had slight lid lag, poor convergence and a fine tremor of the outstretched hands. Schwabach and Rinne tests confirmed the presence of marked bilateral sensor-neural hearing loss. General physical and neurological examinations revealed no other abnormalities.

Hematocrit, hemoglobin, white blood cell count, platelet count, sedimen-

Fig. 2 Technetium 99m brain scintillographs. Three photographs, at varying camera techniques, are taken in each projection. (A and B) Left and right lateral views, during first admission (30 August 1967) exhibiting moderately circumscribed areas of increased radioactivity in left temporal region. (C and D) Left and right lateral views, during second admission (2 April 1968) exhibiting well-defined regions of increased radioactivity in left temporo-parietal region and clearing of the previously left temporal abnormality.

He again appeared inappropriately amused by his plight. He exhibited no response to relatively loud noises. Communication with him was established through writing, gestures and deliberate mouthing of words. He responded appropriately to questions and instructions. His handwriting

was normal. Except for being loud, his speech was normal. Weight 135 pounds. Pulse 110 per minute. Blood pressure 158/70. Pulses were again full to palpation, and there were again no cervical or cranial bruits. The skin was warm and moist. The thyroid gland was diffusely enlarged to an estimated twice normal size, the right lobe being larger than the left. He had slight lid lag, poor convergence, and a fine tremor of the outstretched hands. Schwabach and Rinne tests confirmed the presence of marked bilateral sensori-neural hearing loss. General physical and neurological examinations revealed no other abnormalities.

Hematocrit, hemoglobin, white blood cell count, platelet count, sedimen-

Fig 3 Selected films from percutaneous carotid arteriography (A and B) Left carotid arteriogram, during first admission (11 September 1967) exhibiting vascularity in left temporo-parietal region during arterial phase (A) due to non-filling of the right and posterior parietal branches of the left middle cerebral artery and late retrograde filling of these branches during capillary phase (B) (C) Right carotid arteriogram, during second admission (30 April 1968) exhibiting a small right temporo-parietal region during arterial phase due to non-filling of the distal branches of the right middle cerebral artery

tation rate prothrombin time, partial thromboplastin time serum cholesterol fasting blood sugar 2 hour post prandial blood sugar serum electrolytes, serum calcium and phosphorus, blood urea nitrogen serum creatinine, serum bilirubin, serum alkaline phosphatase, bromsulfalein retention

and urinalysis were either negative or within normal limits. Blood VDRL nonreactive. The LE phenomenon was not observed on four preparations of blood and on one supravital preparation of the buffy coat. Latex globulin slide agglutination test was negative on three occasions. Serum protein electrophoresis revealed albumin 3.7, alpha-1-globulin 0.3, alpha-2-globulin 1.0, beta-globulin 1.1 and gamma-globulin 1.5 gm percent (normal 3.9-5.2, 0.2-0.33, 0.4-0.7, 0.56-0.83 and 0.8-1.5 gm percent respectively). Serum immunoelectrophoresis revealed gamma-G 1150, gamma-A 340 and gamma-M 08 mg percent (normal 1200 ± 228 , 195 ± 91 and 116 ± 55 mg percent respectively). There was slightly increased rouleaux formation on peripheral blood smear. Serum viscosity 1.99 relative to water (normal 1.4-1.8). The Sia test was negative. Protein bound iodine 11.3 micrograms percent. RAI uptake 44% at 24 hours (normal 10-30%). Thyroxine binding index 0.77 (equivalent to T_3 resin uptake of 41.5%). Thyroid scan showed the thyroid gland to be twice normal size, the right lobe being the larger. X-rays of the chest and electrocardiogram were normal.

Ice-water caloric tests produced normal symmetrical responses. Skull X-rays and tangent screen visual fields were normal. Ophthalmodynamometric retinal artery pressures were 70/20 mm Hg bilaterally. Lumbar puncture revealed normal pressure and clear CSF which contained no white blood cells, 12 red blood cells per cu mm, 93 mg percent sugar and 14 mg percent protein. CSF VDRL was nonreactive. EEG on the day of admission was abnormal exhibiting occasional, rhythmical 3-4 Hz activity over the right temporal region (Fig. 1B). Repeat EEG two months later was normal. Technetium-^{99m} brain scan 13 days after admission was abnormal, demonstrating a prominent area of increased uptake in the right temporo-parietal convexity region (Fig. 2C and 2D). Repeat brain scan one month later was equivocal, demonstrating a faint area of increased uptake in the same area. A percutaneous right carotid arteriogram was done six weeks after admission. This exhibited non filling of the distal portions of the right middle cerebral artery with retrograde filling of these vessels during the capillary and early venous phases (Fig. 3C).

Ten weeks after admission, after partial recovery had occurred, Bender-Gestalt Sentence Completion Test and Wechsler Adult Intelligence Scale were administered. Mild receptive and expressive aphasia were again detected. Overall intellectual functioning fell within the normal range with a verbal IQ score of 87, performance IQ 103 and full scale IQ 93, representing declines of 10 and 4 points in the verbal and full scale scores and a point rise in the performance score compared to the previous testing. The Wechsler subtest scores, compared to those previously obtained, indicated a recovered ability to perform psycho-motor tasks and good visual-motor coordination but a significant deterioration in the Digit Span test. This latter combined with his good qualitative performance in the Bender-Gestalt test, was interpreted as being a reflection of his auditory and aphasic problems rather than an indication of memory impairment.

Fig 3 Selected films from percutaneous carotid arteriography (A and B) Left carotid arteriogram, during first demonstration (11 September 1967) exhibiting hypovascularity in left temporo-parietal region during arterial phase (A) due to non-filling of the angular and posterior parietal branches of the left middle cerebral artery and later retrograde filling of these branches during capillary phase (B) (C) Right carotid arteriogram, during second demonstration (30 April 1968) exhibiting hypovascularity in the right temporo-parietal region during arterial phase due to non-filling of the distal branches of the right middle cerebral artery

and urinalysis were either negative or within normal limits. Blood VDRL nonreactive. The LE phenomenon was not observed on four preparations of blood and on one supravital preparation of the buffy coat. Latex globulin slide agglutination test was negative on three occasions. Serum protein electrophoresis revealed albumin 3.7 alpha-1-globulin 0.8 alpha-2-globulin 1.0 beta-globulin 1.1 and gamma-globulin 1.5 gm percent (normal 3.9-5.2, 0.2-0.35, 0.4-0.7, 0.56-0.85 and 0.6-1.5 gm percent respectively). Serum immunoelectrophoresis revealed gamma-G 1150 gamma-A 340 and gamma-M 98 mg percent (normal 1200 ± 228 , 105 ± 91 and 116 ± 55 mg percent respectively). There was slightly increased rouleaux formation on peripheral blood smear. Serum viscosity 1.99 relative to water (normal 1.4-1.8). The Sia test was negative. Protein bound iodine 11.3 micrograms percent. RAI uptake 44% at 24 hours (normal 10-30%). Thyroxine binding index 0.77 (equivalent to T^2 resin uptake of 41.5%). Thyroid scan showed the thyroid gland to be twice normal size the right lobe being the larger. X rays of the chest and electrocardiogram were normal.

Ice-water caloric tests produced normal, symmetrical responses. Skull X rays and tangent screen visual fields were normal. Ophthalmodynamometric retinal artery pressures were 70/20 mm Hg bilaterally. Lumbar puncture revealed normal pressure and clear CSF which contained no white blood cells, 12 red blood cells per cu mm, 85 mg percent sugar and 14 mg percent protein. CSF VDRL was nonreactive. EEG on the day of admission was abnormal, exhibiting occasional, rhythmical 3-4 Hz activity over the right temporal region (Fig. 1 B). Repeat EEG two months later was normal. Technetium-^{99m} brain scan 15 days after admission was abnormal, demonstrating a prominent area of increased uptake in the right temporo-parietal convexity region (Fig. 2 C and 2 D). Repeat brain scan one month later was equivocal, demonstrating a faint area of increased uptake in the same area. A percutaneous right carotid arteriogram was done six weeks after admission. This exhibited non-filling of the distal portions of the right middle cerebral artery with retrograde filling of these vessels during the capillary and early venous phases (Fig. 3 C).

Ten weeks after admission, after partial recovery had occurred, Bender-Gestalt II, Sentence Completion Test, and Wechsler Adult Intelligence Scale were administered. Mild receptive and expressive aphasia were again detected. Overall intellectual functioning fell within the normal range with a verbal IQ score of 87, performance IQ 103 and full scale IQ 93 representing declines of 10 and 4 points in the verbal and full scale scores and a 5 point rise in the performance score compared to the previous testing. The Wechsler subtest scores, compared to those previously obtained, indicated a recovered ability to perform psycho-motor tasks and good visual-motor coordination but a significant deterioration in the Digit Span test. This latter combined with his good qualitative performance in the Bender-Gestalt test, was interpreted as being a reflection of his auditory and aphasic problems rather than an indication of memory impairment.

Fig 4 Pure tone air conduction audiograms. O O = Right ear x-x = Left ear (ASA-511) (A) Prior to onset of illness (3 August 1963) exhibiting normal hearing at all frequencies in both ears. (B) Onset of second admission (20 March 1968) exhibiting marked hearing loss at all frequencies bilaterally (C and D) During recovery phase second admission (8 April 1968 and 3 June 1968) exhibiting in both ears return toward normal, especially at speech frequencies, with persistent marked loss at high frequencies in right ear

Continuous gradual improvement in hearing, the details of which are presented below occurred during hospitalization His resting pulse remained elevated pulse pressure remained wide and he continued to appear clinically hyperthyroid A single dose of 10 millieuries ¹³¹I was administered orally and several weeks later reserpine 0.25 mg daily was added

Tests of language function

Language function (10 weeks after admission, after considerable pure tone sensitivity had returned as demonstrated below)

Articulation was normal Occasional paraphrastic errors persisted during spontaneous speech with repetition and on reading aloud Grammar sentence form and phrasing, cadence of speech, speech rhythm and vocabulary were normal The patient was requested to repeat words pronounced by the examiner first with his eyes open and observing the examiner then with his eyes covered Very few errors occurred when the patient had his eyes open Occasional errors occurred when the patient had his eyes covered and the examiner stood to the left of the patient With eyes covered and examiner to his right the patient was able to repeat very few words accurately He read accurately both quietly and aloud within the limits of his dysphasia, and he exhibited good reading comprehension He exhibited

no abnormalities in writing spontaneously from dictation and by copying. He made no spelling errors. With eyes closed, he was able to identify the sounds of running water and a telephone ringing, but misidentified the crumpling of paper as a rubber band snapping, the snapping of fingers and the clapping of hands as metallic sounds and the sound of a coin being dropped on a desk as a heavy metal sound. Gross clinical testing of sound localization, with patient's eyes covered using loud finger snaps and the clang of a spoon against a metal basin, exhibited highly inaccurate responses in the entire auditory field. Although indicating he clearly heard the sound each time he was able to localize the sound no better than would be expected by chance guessing. The patient had never been able to read music, had never played a musical instrument and stated he had never been able to carry a tune or sing well. On testing, he was able to sing crudely several songs of his choice and several songs given him by title. He was able to repeat phrases of songs sung to him and to hum along with songs being played on the radio. Neither at the time of this examination nor at any other time during his hospitalization was there any evidence of apraxia.

Tests of hearing

The patient had had a normal pure-tone air-conduction audiogram in August 1963 prior to his induction into military service (Fig. 4 A). On the day of his second admission, pure-tone air-conduction audiometry showed a 60 to 85 dB loss at all frequencies in both ears (Fig. 4 B). Pure-tone bone-conduction audiograms at the time of this examination and on all subsequent examinations closely corresponded to the air conduction results, confirming the clinical impression of sensorineural impairment. Serial audiometric testing was accomplished during the second hospitalization. Two representative audiograms from this period of recovery are shown (Fig. 4 C and 4 D). There was a gradual improvement in hearing sensitivity in both ears, the most rapid improvement occurring at the speech frequencies. A considerable loss at the high frequencies persisted in the right ear throughout the period of testing and was still present three months after admission.

Deafness audiometry was attempted shortly after admission but produced such wide excursion that it was felt to be invalid. At the same time electrodermal audiometry was accomplished. No response was obtained at any frequency even at high sound levels, thus confirming the marked hearing loss. Delayed Speech Feedback testing was carried out one week after admission. A Lombard-type response was observed when the feedback was 30 dB HL, binaurally. There was also a change in reading rate. Similar changes were observed when the feedback was at 60 dB HL in the left ear only and at 70 dB HL in the right ear only.

Speech audiometry was carried out on 3 June 1968 after pure tone hearing in the speech frequencies had returned to near-normal levels and

Fig. 4 Pure tone air conduction audiograms. O-O—Right ear x-x—left ear (ASA-51) (A) Prior to onset of illness (3 August 1963) exhibiting normal hearing at all frequencies in both ears. (B) On day of second admission (20 March 1968) exhibiting marked hearing loss at all frequencies bilaterally (C and D) During recovery phase second admission (8 April 1968 and 3 June 1968) exhibiting in both ears a return toward normal, especially at speech frequencies, with persistent marked loss at high frequencies in right ear.

Continuous gradual improvement in hearing, the details of which are presented below occurred during hospitalization. His resting pulse remained elevated, pulse pressure remained wide, and he continued to appear clinically hyperthyroid. A single dose of 10 millicuries ^{131}I was administered orally and several weeks later reserpine 0.25 mg daily was added.

Tests of language function

Language function (10 weeks after admission, after considerable pure tone sensitivity had returned, as demonstrated below)

Articulation was normal. Occasional paraphrasic errors persisted during spontaneous speech with repetition and on reading aloud. Grammar, sentence form and phrasing, cadence of speech, speech rhythm and vocabulary were normal. The patient was requested to repeat words pronounced by the examiner first with his eyes open and observing the examiner then with his eyes covered. Very few errors occurred when the patient had his eyes open. Occasional errors occurred when the patient had his eyes covered and the examiner stood to the left of the patient. With eyes covered and examiner to his right, the patient was able to repeat very few words accurately. He read accurately both quietly and aloud, within the limits of his dysphasia, and he exhibited good reading comprehension. He exhibited

III PSYCHOACOUSTIC FINDINGS

Introduction

In order to highlight abnormalities in psychoacoustic performance data, every procedure administered to our patient was also administered to a normal control subject. The latter was a 25-year-old male with normal hearing and no history or evidence of CNS disorder.

For purposes of comparison the patient is hereinafter referred to as the experimental subject, or simply "E". The normal is hereinafter referred to as the control subject, or simply "C". All of the findings subsequently reported in this monograph, for both E and C, were obtained during the month of June 1968. The following sections compare performance of E and C on listening tasks involving pure-tone audiometry, speech intelligibility, loudness discrimination and auditory temporal order.

Pure tone audiometry

Fig. 5 compares audiograms of E and C obtained by conventional manual technique. C showed relatively normal sensitivity at all test frequencies, but E continued to show the high frequency loss, greater on the right ear illustrated in the audiogram of 3 June 1968 (Fig. 4A). The sensitivity loss had apparently stabilized, and the threshold configuration was reasonably reliable.

Fig. 6, on the other hand, compares manual and Békésy audiometric threshold on E. We note a striking difference between thresholds obtained by the two techniques. On the left ear results are reasonably equivalent by either technique. On the right ear however the Békésy thresholds are

Fig. 5.

Fig. 5. Air-conduction audiograms of E and C obtained by conventional manual technique (June 1968).

Fig. 6.

Fig. 6. Comparison of manual and Békésy air-conduction thresholds in subject E.

when there was no significant speech frequency loss in accordance with the criteria of Street (1957) Spondee threshold testing yielded no accurate responses in the right ear and a threshold hearing level of 16 dB in the left ear PB discrimination testing at 40 dB SL (above spondee threshold) yielded 0% in the right ear and 36% in the left ear PB discrimination was retested on the left ear at sensation levels between 10 and 90 dB and yielded the following scores 10% at 10 dB, 16% at 20 dB, 24% at 30 dB, 36% at 40 dB, 16% at 50 dB 4% at 60 dB 0% at 70 dB and 0% at 80 dB

Electronystagmography

An electronystagmographic examination was carried out by Dr A L Coats, Baylor College of Medicine on 18 June 1968 Caloric responses showed a directional preponderance to the right which was well outside normal limits There was no significant unilateral weakness The optokinetic response was of normal form and showed no significant asymmetry No spontaneous, gaze, or positional nystagmus was observed

when there was no significant speech frequency loss in accordance with the criteria of Street (1957) Spondee threshold testing yielded no accurate responses in the right ear and a threshold hearing level of 10 dB in the left ear PB discrimination testing at 40 dB SL (above spondee threshold) yielded 0% in the right ear and 36% in the left ear PB discrimination was repeated on the left ear at sensation levels between 10 and 80 dB and yielded the following scores 10% at 10 dB 16% at 20 dB, 24% at 30 dB, 36% at 40 dB, 16% at 50 dB 4% at 60 dB 0% at 70 dB and 0% at 80 dB

Electronystagmography

An electronystagmographic examination was carried out by Dr A. C. Coats, Baylor College of Medicine, on 18 June 1968 Caloric responses showed a directional preponderance to the right which was well outside normal limits. There was no significant unilateral weakness. The optokinetic response was of normal form and showed no significant asymmetry. No spontaneous, gaze or positional nystagmus was observed.

III PSYCHOACOUSTIC FINDINGS

Introduction

In order to highlight abnormalities in psychoacoustic performance data, every procedure administered to our patient was also administered to a normal control subject. The latter was a 25-year-old male with normal hearing and no history or evidence of CNS disorder.

For purposes of comparison the patient is hereinafter referred to as the experimental subject, or simply *E*. The normal is hereinafter referred to as the control subject, or simply *C*. All of the findings subsequently reported in this monograph, for both *E* and *C*, were obtained during the month of June, 1968. The following sections compare performance of *E* and *C* on listening tasks involving pure-tone audiometry, speech intelligibility, loudness discrimination and auditory temporal order.

Pure tone audiometry

Fig. 5 compares audiograms of *E* and *C* obtained by conventional manual technique. *C* showed relatively normal sensitivity at all test frequencies, but *E* continued to show the high frequency loss, greater on the right ear illustrated in the audiogram of 3 June 1968 (Fig. 4A). The sensitivity loss had apparently stabilized, and the threshold configuration was reasonably reliable.

Fig. 6, on the other hand, compares manual and Békésy audiometric thresholds on *E*. We note a striking difference between thresholds obtained by the two techniques. On the left ear results are reasonably equivalent by either technique. On the right ear however the Békésy thresholds are

Fig. 5

Fig. 6

Fig. 6. Comparison of manual and Békésy air-conduction thresholds for subject *E*.

when there was no significant speech frequency loss in accordance with the criteria of Street (1937) Spondee threshold testing yielded no accurate responses in the right ear and a threshold hearing level of 16 dB in the left ear PB discrimination testing at 40 dB SL (above spondee threshold) yielded 0% in the right ear and 36% in the left ear PB discrimination was retested on the left ear at sensation levels between 10 and 80 dB and yielded the following scores: 10% at 10 dB, 16% at 20 dB, 24% at 30 dB, 36% at 40 dB, 16% at 50 dB, 4% at 60 dB, 0% at 70 dB and 0% at 80 dB

Electronystagmography

An electronystagmographic examination was carried out by Dr A. C. Coats, Baylor College of Medicine, on 18 June 1968 Caloric responses showed a directional preponderance to the right which was well outside normal limits There was no significant unilateral weakness The optokinetic response was of normal form and showed no significant asymmetry No spontaneous, gaze or positional nystagmus was observed

Fig. 8

Fig. 8. Performance-Intensity (PI) functions for monosyllable (PB) word lists.

Fig. 9

Fig. 9. Performance-Intensity (PI) functions for synthetic sentence identification (SSI) lists.

Although this situation rendered conventional spondee threshold testing ambiguous, we attempted to determine at least a rough approximation by repeated presentation of the single spondee word "cowboy". Spondee identification thresholds, or more properly "cowboy" thresholds obtained in this fashion were 20 dB HL for the left ear and 66 dB HL for the right ear. The 20 dB level for the left ear agrees quite well with the average pure tone hearing level of 18 dB. On the right ear however the threshold for "cowboy" was 44 dB poorer than the average pure-tone hearing level by manual audiometry but corresponded well to the average pure-tone hearing level by Bekésy audiometry (61 dB).

We turned next to a synthetic sentence identification (SSI) task (Jerger *et al.* 1958). Fig. 9 shows PI functions of both subjects for sentences presented in quiet. C's performance rose rapidly to 100% correct on both ears. E's performance on the left ear illustrated the unique improvement typically found for sentence materials. Although his maximum PB score was only 36% sentence identification scores were 100% at approximately 40 dB SPL and above. On E's right ear however the maximum sentence identification score was only 30%. The pattern of the PI function for sentences in the right ear closely resembled the pattern of the PI function for PB words in the left ear. Similar maxima and a "roll-over" effect at intensities greater than 80 dB SPL were noted. Apparently E could not take advantage of the additional contextual clues and redundancy of the sentence message set in the right ear. E stated that sentences presented to this ear sounded like "short wave radio". He stated that occasionally he heard speech, but that "the rest of it is buzz". On further questioning he said that the speech sounded like two voices, one high and one low. He could understand the high voice but the low voice muffled what he could hear.

Fig. 7 Comparison of Békésy audiograms of E and C (int \rightarrow cont) (A) Left ear (B) Right ear

substantially poorer than the conventional manual thresholds over the range from 500 to 2000 Hz. The Békésy thresholds plotted in Fig. 8 were obtained on a standard Békésy audiometer (Crasson-Stadler model E 800). Frequency changed at the rate of one octave/min, intensity changed at the rate of 2.5 dB/sec, and the signal was periodically interrupted at the rate of 25:1 p:s.

We believe that the threshold differences between manual and Békésy results on the right ear may be accounted for by differences in the "on duration" of signal presentation under the two methods. For Békésy audiometry the on-duration was approximately 200 msec, whereas for manual audiometry the on-duration of each signal was typically greater than one second. In chapter V we present data indicating that, in E's right ear, 200 msec is an insufficient duration to reflect maximum sensitivity.

Fig. 7 compares actual Békésy tracings of E and C on left and right ears. In all cases we note a type I tracing (Jerger 1960c). Thresholds for continuous and interrupted tones overlap. There is no evidence of the excessive adaptation to sustained stimulation characterizing eighth nerve and brain stem disorders.

Speech audiometry

Fig. 8 compares E and C on performance-intensity (PI) functions for lists of 25 monosyllable (PB) words. The PI function for E's left ear rises to a maximum of 36% then falls off rapidly as speech intensity is increased. On the right ear there is no response to PB words at any level.

It has been previously noted to be sure that impaired speech intelligibility in the presence of relatively normal sensitivity is characteristic of central auditory disorders, but in this patient the discrepancy between sensitivity and intelligibility is particularly dramatic, especially on the right ear. In spite of the average pure tone hearing level (500-2000 Hz) of 22 dB the PB score was 0%. In response to PB words E stated that he heard only a buzz in the right ear.

Fig. 8.

Fig. 8 Performance-Intensity (PI) functions for monosyllabic (PB) word lists.

Fig. 9.

Fig. 9 Performance-Intensity (PI) functions for synthetic sentence identification (SSI) lists.

Although this situation rendered conventional spondee threshold testing ambiguous, we attempted to determine at least a rough approximation by repeated presentation of the single spondee word "cowboy". Spondee identification thresholds, or more properly "cowboy" thresholds obtained in this fashion were 20 dB HL for the left ear and 66 dB HL for the right ear. The 20 dB level for the left ear agrees quite well with the average pure tone hearing level of 18 dB. On the right ear however the threshold for "cowboy" was 44 dB poorer than the average pure-tone hearing level by manual audiometry but corresponded well to the average pure-tone hearing level by Békésy audiometry (61 dB).

We turned next to a synthetic sentence identification (SSI) task (Jerger *et al.*, 1968). Fig. 9 shows PI functions of both subjects for sentences presented in quiet. C's performance rose rapidly to 100% correct on both ears. E's performance on the left ear illustrated the unique improvement typically found for sentence materials. Although his maximum PB score was only 35% sentence identification scores were 100% at approximately 40 dB SIL and above. On E's right ear however the maximum sentence identification score was only 30%. The pattern of the PI function for sentences in the right ear closely resembled the pattern of the PI function for PB words in the left ear. Similar maxima and a "roll-over" effect at intensities greater than 80 dB SPL were noted. Apparently E could not take advantage of the additional contextual clues and redundancy of the sentence message set on the right ear. E stated that sentences presented to this ear sounded like "short wave radio". He stated that occasionally he heard speech, but that "the rest of it is buzz". On further questioning he said that the speech sounded like two voices, one high and one low. He could understand the high voice but the low voice muffled what he could hear.

Fig. 10 Psychometric functions for discrimination of loudness change at 250 Hz.

Fig. 11 Psychometric functions for discrimination of loudness change at 500 Hz.

Fig. 12 Psychometric functions for discrimination of loudness change at 1000 Hz.

Loudness discrimination

The ability to detect small changes in sound intensity was measured by the quantal psychophysical method (Stevens *et al.*, 1941). Short intensity increments were added to a steady state pure-tone signal at aperiodic intervals. Each subject responded by pushing a button whenever he detected a change in the loudness of the steady tone. Increment duration was 200 msec, with a rise-decay time of 25 msec. The interval between successive increments was either 2, 3 or 5 sec determined by a random schedule. Each of the three intervals occurred with equal probability. Increments were presented in blocks of 20. Increment size was constant within each block, but varied over successive blocks in order to construct psychometric functions over the response range from 0 to 100% correct detection. The SPL of the steady state signal was held constant at 90 dB for four test frequencies: 250 Hz, 500 Hz, 1000 Hz and 2000 Hz.

Fig. 10 shows results at 250 Hz for both right and left ears of E and C. We note that C reaches 100% correct detection on either ear for an intensity increment (ΔI) of only 2 dB. Subject E does almost as well as C on the left ear but the psychometric function for the right ear reflects dramatically poor loudness discrimination. An intensity increment of 12 dB is required to reach 100% correct detection.

Figs. 11, 12 and 13 show analogous results at 500, 1000 and 2000 Hz. The pattern of results illustrated in Fig. 10 is repeated. E performs about as well as C on his left ear but shows relatively poorer loudness discrimination on his right ear.

Fig. 14 shows results at 1000 Hz when ΔI is held constant at 1 dB, and the

Fig. 13

Fig. 13. Psychometric functions for discrimination of loudness change at 2000 Hz.

Fig. 14

Fig. 14. Loudness discrimination as a function of signal level for $\Delta I = 1$ dB.

SPL of the steady-state carrier tone is varied (the paradigm of the SISI test) C reaches 100% correct detection at an SPL of 80–90 dB. E never does reach 100% detection, but attains a maximum of 80% on the left ear at about 90 dB SPL. On E's right ear however performance never exceeds 10% even at 110 dB SPL.

These results are in accord with Hodgson's (1967) observations on a patient with left hemispherectomy. Hodgson noted reduced SISI scores at high intensity levels on the ear opposite the affected side of the brain. We are unable however to reconcile these findings with Swisher's (1967) report of bilateral hypersensitivity to intensity change following left temporal lobe excision. The hypersensitivity was observed post-operatively but not pre-operatively. Measurement was, unfortunately confined to 2000 Hz, a frequency at which the present results show a minimum difference between E's left and right ears.

Temporal order

Temporal ordering refers to the patient's ability to identify the order in which different auditory events occur in time. The phenomenon is of particular interest here because of Efron's (1963) recent report that the capacity to order temporally distinct events may be profoundly disturbed in aphasic patients, especially those of the expressive variety, and because of the findings of Hirsh and Sherrick (1961) that the minimum temporal separation required for correct ordering is remarkably independent of sense modality in the normal subject.

Unfortunately Efron, in his study of aphasics, and Hirsh and Sherrick, in their study of normals, used distinctly different signal configurations.

Fig. 15.

Fig. 16

Fig. 15. Two experimental paradigms for the measurement of temporal order

Fig. 16. Results for temporal order measured by paradigm I and method of limits.

In order to gather data suitable for comparison with both studies, therefore we found it necessary to measure temporal order by two methods.

Fig. 15 illustrates the two different signal configurations employed. Paradigm I is roughly analogous to Efron's paradigm although there are differences in detail. Efron's signals were pulses at frequencies of 250 and 2500 pps presented for 10 msec, whereas we used tones of 400 and 800 Hz presented for 40 msec. Paradigm II is analogous to the paradigm of Hirsch and Sherrick. The principal difference is that while they used a 500 msec duration for the longer tone, we found it necessary to increase the duration to 1000 msec, in order to accommodate the extraordinarily large temporal separations required by E for correct identification of order. From the listener's standpoint the crucial difference between paradigms I and II is that in I both onset and termination of F_2 vary as a function of Δt , whereas, in II only the onset of F_2 varies. Both tones end simultaneously. Paradigm I thus provides at least two separate clues to order whereas paradigm II provides only one.

For both paradigms testing was carried out by a method of limits technique. Signal pairs were presented at 8 sec intervals at an SPL of 80 dB. After each pair had been presented the subject indicated verbally whether the first or leading tone was the high pitched or the low pitched member of the pair. The actual assignment of high or low pitched tones as the leading signal was randomly varied over successive presentations with the *a priori* constraint of equal probability. Following a method of limits technique the size of Δt was both decreased from an easily identified point and increased from zero difference until descending and ascending limits had been defined. The midpoint between these two points was defined as the

Fig. 18 Result for temporal order measured by paradigm II and 2AFC method.

minimum separation for temporal order (Δt) and is so labelled on subsequent figures.

Fig. 16 shows results obtained under paradigm I for both monaural and binaural presentations. In the monaural conditions both tones were presented to the same ear. In the binaural conditions the lower of the two pitches always went to one ear and the higher to the other. We see in Fig. 16, striking confirmation of Efron's findings. Whereas C can resolve temporal order in 10-25 msec E requires substantially larger temporal separation, in the range from 300 to 600 msec. The logarithmic display of Δt necessary to encompass results for C and E in the same figure actually minimizes the disparity between the two subjects. A linear plot of Δt would more effectively dramatize the difference.

Fig. 17 shows results obtained under paradigm II. Here E does somewhat better than under paradigm I, but Δt is never less than 200 msec under any condition. Subject C, on the other hand, never requires more than a 40 msec separation.

In order to ensure that E's performance was not confounded by the exact psychophysical procedure (limits) employed to define Δt the entire set of measurements shown in Fig. 17 was repeated using a two-alternative, forced-choice (2AFC) technique. Over blocks of 20 signal pairs Δt was held constant, and either the higher or lower pitch occurred as the leading sound with random but equal probability. The size of Δt was varied over successive blocks to define a complete psychometric function. The threshold for temporal order was defined as the 75% point of this function. Results are shown in Fig. 18. We can see no important differences relating to type of psychophysical method employed.

Fig. 15.

Fig. 16.

Fig. 15. Two experimental paradigms for the measurement of temporal order.

Fig. 16. Results for temporal order measured by paradigm I and method of limits.

In order to gather data suitable for comparison with both studies, therefore we found it necessary to measure temporal order by two methods.

Fig. 15 illustrates the two different signal configurations employed. Paradigm I is roughly analogous to Efron's paradigm although there are differences in detail. Efron's signals were pulses at frequencies of 250 and 2500 pps presented for 10 msec, whereas we used tones of 400 and 600 Hz presented for 40 msec. Paradigm II is analogous to the paradigm of Hirsch and Sherrick. The principal difference is that while they used a 500 msec duration for the longer tone we found it necessary to increase the duration to 1000 msec, in order to accommodate the extraordinarily large temporal separations required by E for correct identification of order. From the listener's standpoint the crucial difference between paradigms I and II is that in I both onset and termination of F_2 vary as a function of Δt whereas, in II only the onset of F_2 varies. Both tones end simultaneously. Paradigm I thus provides at least two separate clues to order whereas paradigm II provides only one.

For both paradigms testing was carried out by a method of limits technique. Signal pairs were presented at 8 sec intervals at an S.L.L. of 80 dB. After each pair had been presented the subject indicated verbally whether the first or leading tone was the high pitched or the low pitched member of the pair. The actual assignment of high or low pitched tones as the leading signal was randomly varied over successive presentations with the *a priori* constraint of equal probability. Following a method of limits technique the size of Δt was both decreased from an easily identified point and increased from zero difference until descending and ascending limits had been defined. The midpoint between these two points was defined as the

impairment in temporal pattern discrimination after bilateral ablation of auditory cortex.

It is also noteworthy that E's impairment in temporal ordering does not show the ear specificity previously demonstrated for both speech intelligibility and loudness discrimination. In both of these areas results for the right ear were uniformly poorer than results for the left ear. In temporal ordering tasks, however, we can see no consistent differences among right ear-left ear or binaural results.

It is of some interest to ask, therefore, whether E's performance is a manifestation of some more general loss in sequential discrimination not specific to auditory signals. To this end, we investigated temporal order for visual events. Two 12 volt light bulbs, each approximately 1 cm in diameter were mounted horizontally in a box 5 inches high and 6 inches long. The horizontal separation between bulbs was 1.5 inches. One bulb had a red shield, the other a green shield. Subjects were seated approximately 1 meter from the visual array. Temporal intervals between light signal onsets were varied according to paradigm II, and the subject responded either red-green, green-red, or same. Thresholds were defined by a method of limits technique. There was no difference between C and E on this task. Both subjects correctly ordered visual signals at a temporal separation of 20-30 msec. We conclude therefore, that E's temporal ordering deficit is a specifically auditory impairment.

Summary

Approximately three months after this patient's second cerebral insult auditory sensitivity as measured by conventional manual audiometry had returned to relatively normal levels in the region below 2000 Hz. Above this point, however, a bilateral high frequency loss, somewhat more severe on the right ear persisted.

In contrast to the bilateral symmetry suggested by the manual results, Békésy audiometry revealed substantially poorer sensitivity on the right ear. Both ears showed type I tracings.

Performance-intensity functions for phonetically balanced (PB) word list showed extremely impaired speech understanding on both ears, with poorest performance on the right ear. Performance-intensity functions for synthetic sentences (SSI) were normal on the left ear but severely impaired on the right ear.

Loudness discrimination, as measured by the quantal psychophysical method, was normal on the left ear but severely impaired on the right ear.

Perception of auditory temporal order was severely impaired in both ears. Whereas the control subject could correctly order events differing by 10-40 msec the experimental subject required temporal delays of 200-300 msec for successful performance. The effect was invariant over two test paradigms and two psychophysical methods. The perception of temporal order for visual events was unimpaired.

Table 1 *Temporal order thresholds (Δt in msec) of experimental (E) and control (C) subjects for four different frequency pairs*

Data obtained by paradigm II and method of limits.

Frequency pairs	Subject	Monaural		Binaural	
		LE	RE	LE low	RI-low
400-600 Hz	E	300	300	300	300
	C	25	25	40	35
800-1200 Hz	F	300	400	CNE ^a	350
	C	25	20	35	40
2500-3500 Hz	F	600	CNE ^a	CNE ^a	CNE ^a
	C	20	20	35	35
500-2000 Hz	L	250	250	300	250
	C	20	20	25	25

^a Could not establish (see text)

In order to determine the generality of these differences across the frequency range additional data were gathered by the method of limits for frequency pairs of 800-1200 Hz, 2500-3500 Hz, and 500-2000 Hz. The latter pair was included in order to ensure that E's poor performance was not the result of inability to resolve the approximately one-half octave pitch differences used to this point.

Table 1 summarizes values of Δt obtained for these various frequency combinations. Entries labelled "CNE" indicate conditions under which E could not order the two events correctly even with a temporal separation in excess of 800 msec. In these conditions he insisted that he heard only a series of pulses followed by a tone. When the signals were presented binaurally he heard pulses on the left ear and tone on the right ear. The pulses always preceded the tone.

The data of Table 1 reveal a consistent impairment in temporal resolution across the frequency range present even when the pitch difference is two octaves (500-2000 Hz). Furthermore, comparison of Fig. 16 and 17 reveals that the effect is largely independent of the exact methodology employed to measure temporal order.

These results are entirely consistent with the previous findings of Efron (1963) and Edwards and Auger (1965) on patients with unilateral hemispheric lesions. Efron for example obtained Δt 's ranging from 150-350 msec in patients with receptive aphasia and from 150-700 msec in patients with expressive aphasia. As noted earlier (Chapter II) our patient E, showed some aphasic symptoms following his initial cerebral accident but was largely symptom free at the time of this testing. The present results are also consistent with recent findings in animals. Jerison and Neff (1955), Diamond and Neff (1957), Neff (1961) and Wegener (1968) all report im-

Fig. 19 Arrangement of apparatus for the measurement of absolute sound localization. Subject seated, blindfolded, at the center of anechoic chamber. A loudspeaker is mounted on boom at radius of 8' from the center of the subject's head.

(1936) and Butler *et al* (1967) also found a decline in localization accuracy in the vicinity of 2000 to 4000 Hz.

For subject E sound localization accuracy was consistently poor for all signals. Errors as large as 180° were observed. In addition, we did not find the improved localization accuracy for sawtooth noise and click signals that we observed in the control subject. As seen in Fig. 20 the two judgments that were obtained at each azimuth were occasionally quite different. For example in Fig. 20 E, when the sound source was presented at 30° on the left, E responded "right 45°" on the first trial and "left 90°" on the second trial. Subject E volunteered that 4000 Hz was more difficult to localize than either 400 Hz or 1000 Hz. He stated that the 4000 Hz signal "starts out sounding like a buzz, then smooths off into a high-pitched sound."

A significant disturbance of sound localization ability has been reported previously in animals with bilateral temporal lobe ablations (Neff, Arnott, and Fisher 1950; Neff, Fisher, Diamond, and Yela, 1956; Neff 1961; Masterton and Diamond 1964; Wegner 1968). In addition, a few patients with bilateral hemispheric lesion have been studied and were found to have a severe or total loss of sound localization ability (Weber 1947; Sanchez-Leng and Foster 1958).

Fig. 21 summarizes non-directional error in sound localization for both subjects. For each signal the discrepancy between actual and apparent location of the sound was averaged across both trials at all 12 azimuths. For this analysis errors were averaged without regard to their direction. This average error is, therefore non-directional.

For subject C non-directional errors for pure tone signal became larger

IV AUDITORY LOCALIZATION

Absolute localization

In order to study the absolute localization of actual sound sources in space a loudspeaker was mounted on a boom and pivoted so that it travelled the perimeter of a circle 16 feet in diameter (Fig. 19). The path of the loudspeaker was calibrated in 1 steps.

Testing was conducted in an anechoic chamber (20 feet by 16 feet 8 inches). The subject was seated in a dental chair at the center of the circle 8 feet from the sound source. The height of the subject's chair was adjusted so that the tragus was in the same horizontal plane as the center of the loudspeaker cone. The headrest of the dental chair was then adjusted so that the subject's head fit comfortably into it. The subject was instructed to maintain this head position throughout each experimental run. No further attempt was made to restrict head movement. During all test conditions, the subject wore a blindfold.

Localization of pure tone click and sawtooth noise signals was tested at 15 intervals from 90° left to 90° right (see Fig. 19). For each signal presentation the subject verbally reported the perceived location of the sound to the nearest 5°. Interval. Two separate judgements were obtained at each test azimuth. Signals were presented at 60 dB SL. For sawtooth noise and pure tone signals, duration was 10 sec with 100 msec rise-decay time. For click signals, a click train with a repetition rate of 2 clicks per sec was presented for a total duration of 10 sec. The train was generated by rectangular pulses of 1 msec duration.

Fig. 20 presents results for both subjects as a function of signal azimuth for clicks (a) sawtooth noise (b) 400 Hz (c) 1000 Hz (d) and 4000 Hz (e). Data are reported as apparent or perceived azimuth in degrees. The diagonal line represents perfect agreement between the actual location of the sound source and the subject's perceived location.

For subject C, localization was most accurate for click and sawtooth noise signals. As seen in Fig. 20 A and 20 B all responses cluster around the line representing perfect agreement. This finding is consistent with previous studies of sound localization in space (Stevens and Newman 1936; Sandel *et al.* 1955). For example, Stevens and Newman reported that subjects localized noise as more readily than pure tone signals.

Subject C's precision in localizing pure tone signals varied as a function of frequency. Localization errors were reasonably small at 400 Hz and 1000 Hz, but became noticeably larger at 4000 Hz. Stevens and Newman

Fig. 19 Arrangement of apparatus for the measurement of absolute sound localization. Subject is seated, blindfolded, in the center of a sound chamber. A loudspeaker is mounted on a boom at a radius of 80 cm from the center of the subject's head.

(1935) and Butler *et al.* (1967) also found a decline in localization accuracy in the vicinity of 2000 to 4000 Hz.

For subject E, sound localization accuracy was consistently poor for all signals. Errors as large as 180° were observed. In addition, we did not find the improved localization accuracy for sawtooth noise and click signals that we observed in the control subject. As seen in Fig. 20 the two judgments that were obtained at each azimuth were occasionally quite different. For example in Fig. 20 E, when the sound source was presented at 30° on the left, E responded right 45° on the first trial and left 90° on the second trial. Subject E volunteered that 4000 Hz was more difficult to localize than either 400 Hz or 1000 Hz. He stated that the 4000 Hz signal "sounded like a buzz, then morphs off into a high pitched sound."

A profound disturbance of sound localization ability has been reported previously in animals with bilateral temporal lobe ablation (Neff, Arnold, and Fisher 1950; Naff, Fisher, Diamond, and Yela, 1956; Neff 1961; Masterton and Diamond 1964; Wegner 1968). In addition, a few patients with bilateral hemispheric lesions have been studied and were found to have severe or total loss of sound localization ability (Weber 1947; Sanchez-Lang and Forster 1958).

Fig. 21 summarizes non-directional error in sound localization for both subjects. For each signal the discrepancy between actual and apparent location of the sound was averaged across both trials at all 13 azimuths. For this analysis errors were averaged without regard to their direction. This average error is therefore non-directional.

In subject C, non-directional errors for pure tone signals became larger

IV AUDITORY LOCALIZATION

Absolute localization

In order to study the absolute localization of actual sound sources in space, a loudspeaker was mounted on a boom and pivoted so that it travelled the perimeter of a circle 16 feet in diameter (Fig. 19). The path of the loudspeaker was calibrated in 1° steps.

Testing was conducted in an anechoic chamber (20 feet by 16 feet 8 inches). The subject was seated in a dental chair at the center of the circle 8 feet from the sound source. The height of the subject's chair was adjusted so that the tragus was in the same horizontal plane as the center of the loudspeaker cone. The headrest of the dental chair was then adjusted so that the subject's head fit comfortably into it. The subject was instructed to maintain this head position throughout each experimental run. No further attempt was made to restrict head movement. During all test conditions, the subject wore a blindfold.

Localization of pure tone click and sawtooth noise signals was tested at 15° intervals from 90° left to 90° right (see Fig. 19). For each signal presentation the subject verbally reported the perceived location of the sound to the nearest 5° interval. Two separate judgements were obtained at each test azimuth. Signals were presented at 60 dB SPL. For sawtooth noise and pure tone signals, duration was 10 sec with 100 msec rise-decay times. For click signals, a click train with a repetition rate of 2 clicks per sec was presented for a total duration of 10 sec. The train was generated by rectangular pulses of 1 msec duration.

Fig. 20 presents results for both subjects as a function of signal azimuth for clicks (a) sawtooth noise (b) 400 Hz (c) 1000 Hz (d) and 4000 Hz (e). Data are reported as apparent or perceived azimuth in degrees. The diagonal line represents perfect agreement between the actual location of the sound source and the subject's perceived location.

For subject C, localization was most accurate for click and sawtooth noise signals. As seen in Fig. 20 A and 20 B all responses cluster around the line representing perfect agreement. This finding is consistent with previous studies of sound localization in space (Stevens and Newman, 1936; Sandel *et al.* 1955). For example, Stevens and Newman reported that subjects localized noises more readily than pure tone signals.

Subject C's precision in localizing pure tone signals varied as a function of frequency. Localization errors were reasonably small at 400 Hz and 1000 Hz, but became noticeably larger at 4000 Hz. Stevens and Newman

Fig. 19. Arrangement of apparatus for the measurement of absolute sound localization. Subject is seated, blindfolded, in the center of a circular chamber. A loudspeaker is mounted on a boom at a radius of 8' from the center of the subject's head.

(1936) and Butler *et al* (1967) also found a decline in localization accuracy in the vicinity of 2000 to 4000 Hz.

For subject E sound localization accuracy was consistently poor for all signals. Errors as large as 180° were observed. In addition we did not find the improved localization accuracy for sawtooth noise and click signals that we observed in the control subject. As seen in Fig. 20 the two judgments that were obtained at each azimuth were occasionally quite different. For example, in Fig. 20 E, when the sound source was presented at 30° on the left, E responded "right 45°" on the first trial and "left 90°" on the second trial. Subject E volunteered that 4000 Hz was more difficult to localize than either 400 Hz or 1000 Hz. He stated that the 4000 Hz signal starts out sounding like a buzz, then smooths off into a high pitched sound."

A profound disturbance of sound localization ability has been reported previously in animals with bilateral temporal lobe ablations (Neff, Arnott, and Fisher 1959; Neff, Fisher, Diamond, and Yela, 1958; Neff 1961; Masterton and Diamond, 1964; Wegner 1968). In addition, a few patients with bilateral hemispheric lesions have been studied and were found to have a severe or total loss of sound localization ability (Weber 1947; Sanchez-Longo and Forster 1958).

Fig. 21 summarizes non-directional error in sound localization for both subjects. For each signal the discrepancy between actual and apparent location of the sound was averaged across both trials at all 12 azimuths. For this analysis errors were averaged without regard to their direction. This average error is, therefore, non-directional.

For subject C non-directional errors for pure tone signals became larger

Fig. 20 Absolute judgement of sound location at 13 azimuth varying from 90° R to 90° L. (A) Click trains, (B) sawtooth noise (C) 400 Hz, (D) 1000 Hz, (E) 4000 Hz.

as frequency increased. As shown in Fig. 21 the average error was approximately 17° at 400 Hz, 10° at 1000 Hz, and 21° at 4000 Hz. These data closely correspond to the findings of Stevens and Newman (1934) for localization of pure tones in the horizontal plane. They reported an average error of approximately 12° at 400 Hz, 13° at 1000 Hz, and 20° at 4000 Hz.

Subject C's a large non-directional error for click and sawtooth noise signal illustrates the fact that complex sounds are more accurately localized than pure tones. The average localization error was only 4° for sawtooth noise and 8.6° for click trains. These data are in accordance with the findings of Stevens and Newman (1936) and Sanchez-Longo and Forster (1938).

Results for E also showed a relation between error and signal frequency. Localization accuracy was poorest at 4000 Hz. Although errors were unusually large for all sound sources, the average error at this frequency was 71°. Average errors for other test signals were reasonably constant, ranging from approximately 36° to 49°. These results again dramatically illustrate the marked difficulty in sound localization experienced by E.

Fig. 22 summarizes directional error or bias in sound localization for both subjects. For this analysis the direction of the discrepancy between actual and apparent location of the sound was taken into account. This average error is, therefore, directional in the sense that it reflects systematic directional bias in localization. For subject C there was a consistent directional error to the left. Although this bias was small, less than 10° for

Fig. 1

Fig. 22

Fig. 21 Non-directional error in absolute localization, averaged across trials and azimuths, for all signals.

Fig. 22 Directional error in absolute localization, averaged across trials and azimuths, for all signals.

all signals, apparent locations tended to be left of the test azimuth. With the exception of click signals, a consistent bias to the left was also observed for subject E. The directional error for this subject was small for 1000 Hz and sawtooth noise signals. Although the average non-directional error for these signals was large, approximately 36 to 40, the directional error was only about 10. A large bias to the left, approximately 26 to 31, was found at 400 Hz and 4000 Hz. Curiously, a bias of 16 to the right was found for click signals.

Fig. 23 shows non-directional error averaged across all signal sources as a function of signal azimuth. Fig. 24 shows the analogous average directional error as a function of azimuth. As seen in Fig. 23, C's performance was most accurate in the region directly in front of the subject or 0 azimuth. Stevens and Newman (1938) also found that localization errors were smallest for sounds in the median plane. The average non-directional error of subject C ranged from approximately 6 to 12 in the right auditory field. There was curiously poor performance between azimuths of 15 and 60 in the left field. In this range the average non-directional error was approximately 15 to 22. For subject E accuracy was poor at all azimuths. The average non-directional error ranged from 21 to 69. In contrast to C, the most accurate judgements were obtained at 45° on the left. Accuracy became progressively poorer as the test azimuth moved away from this point.

In general, directional errors for C seen in Fig. 24 showed a left bias for signals presented in the left auditory field and a right bias for signals in the right auditory field. However, the opposite effect was seen for signals presented at 0° azimuth. Apparently C judged signals presented at 90°

Fig. 22.

Fig. 22. Non-directional error in absolute localization, averaged across trials and signal conditions, as a function of azimuth.

Fig. 24.

Fig. 24. Directional error in absolute localization, averaged across trials and signal conditions, as a function of azimuth.

to be more medially located. Butler *et al.* (1967) also found that judgements for sound originating at the most peripheral positions were displaced toward the median plane. For subject C, judgements in the right auditory field were more accurate than judgements in the left field. In addition, there was a slight bias to the left for signals presented at 0°. Directional errors were however generally small. Directional errors for subject E were smallest for judgements from approximately 30° on the left to 30° on the right. In addition there was a bias to the left for all judgements from 15° in the left auditory field to 90° in the right field. The magnitude of the directional error increased dramatically as the test azimuth moved to 90° on the right. Apparently sounds were generally perceived in the median plane or left auditory field even though signals were presented at the extreme right periphery. We see also the curious bias to the right for signals presented in the extreme left periphery that was observed in the control subject. Apparently for both subjects, test signals presented at 90° in either field were usually judged to be more medially located.

Finally in order to ensure that E's poor performance on sound localization tasks was not confounded by the verbal response mode employed, the entire procedure for effect trials was repeated with the addition of a purely motor response. In addition to his verbal report E was instructed to point, with a yardstick, to the apparent sound location. This modifica-

Fig. 25 Effect of signal duration in intracranial localization for subject E. (A) 400 Hz. (B) 1000 Hz.

tion in procedure had no effect on performance. There was little discrepancy between verbal report and indication by pointing, and accuracy of localization was not improved.

During this procedure however F startled us by asking, "Should I point to where the sound begins or where it ends?" Upon further questioning E reported that sounds "moved" during the 10 sec presentation interval. Consistent judgements were difficult because signals were never "still".

Intracranial localization

In further pursuit of this traveling sound phenomenon, signals were presented binaurally to E through earphones, and intracranial localization was studied as a function of signal duration.

A single pure-tone signal was split and delivered to matched, phased earphones at equal SPL (80 dB). Signals were presented once every 2 sec at on-durations ranging from 20 to 1000 msec. The rise-decay time of each signal was 5 msec. After each signal presentation E was asked to report the perceived location of the sound along an arc from ear to ear. The arc was divided into two quadrants from midline to left ear level (0 to L 90°) and midline to right ear level (0 to R 90°). The subject reported location in respective quadrants in 15 steps.

Fig. 25 shows results at 400 Hz (a) and 1000 Hz (b). At 400 Hz, two judgements were obtained for on-durations between 20 and 100 msec. For all other signal presentations only one judgement was obtained. As shown in Fig. 25 the perceived movement of sounds with on-durations between 20 and 100 msec appears to be random. Apparently sounds travelled in both directions and occasionally in an oscillatory manner. For example in Fig. 25 A, at an on-duration of 60 msec E reported that the sound began

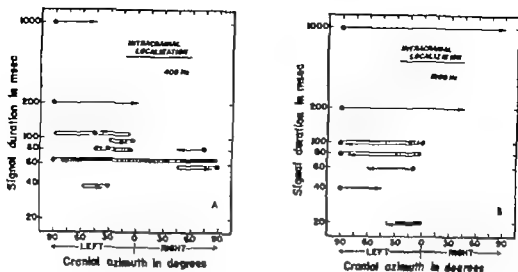

Fig 25 Effect of signal duration in intracranial localization for subject E. (A) 400 Hz, (B) 1000 Hz.

tion in procedure had no effect on performance. There was little discrepancy between verbal report and indication by pointing, and accuracy of localization was not improved.

During this procedure however E startled us by asking, "Should I point to where the sound begins or where it ends?" Upon further questioning E reported that sounds "moved" during the 10 sec presentation interval. Consistent judgements were difficult because signals were never still.

Intracranial localization

In further pursuit of this traveling sound phenomenon signals were presented binaurally to E through earphones, and intracranial localization was studied as a function of signal duration.

A single pure-tone signal was split and delivered to matched phased earphones at equal SPL (80 dB). Signals were presented once every 2 sec at on-durations ranging from 20 to 1000 msec. The rise-decay time of each signal was 5 msec. After each signal presentation E was asked to report the perceived location of the sound along an arc from ear to ear. The arc was divided into two quadrants from midline to left ear level (0 to L 90) and midline to right ear level (0 to R 90). The subject reported location in respective quadrants in 15 steps.

Fig. 25 shows results at 400 Hz (a) and 1000 Hz (b). At 400 Hz, two judgements were obtained for on-durations between 20 and 100 msec. For all other signal presentations, only one judgement was obtained. As shown in Fig. 25 the perceived movement of sounds with on-durations between 20 and 100 msec appears to be random. Apparently sounds travelled in both directions and occasionally in an oscillatory manner. For example in Fig. 25 A at an on-duration of 80 msec E reported that the sound began

Table 2. Visual perception of angles (error in degrees)

Subject	Vertical	Horizontal
E	1.35 L	1.0 L
H	1.20 L	1.0 L

speaker was placed at 0 and 15 on the left. Judgements at all other test azimuths were approximately 70 to 80% correct. The average percent correct response at all test azimuths for this subject was 81%. In contrast, subject E's performance was quite poor. E achieved only 48% correct for all azimuths. Like C, however, E's performance was best for judgements in the median plane, or 0. Mills (1958) also found that performance was most accurate in the region straight ahead of the subject for judgements of minimum audible angle.

Performance as a function of test azimuth can be seen more clearly in Fig. 28. These results were obtained by averaging performance in the right and left auditory fields at each azimuth. For both subjects, performance was best for signals presented at 0. Then accuracy systematically decreased as the test azimuth increased toward 75. C's responses ranged from 100% correct at 0 to 72% correct at 75. E's responses however were unusually poor ranging from approximately 60% at 0 to 40% at 75. These results, while poorer than C's are well above the chance performance level (33%). The importance of these results lies principally in what they do not show. We fail to see evidence, in E's performance of any systematic differences between fields or among azimuths. His pattern of performance is similar to C's but displaced downward considerably.

Finally in order to ensure that E's performance on the relative localization task was specifically auditory and not the result of a more generalized deficit in the judgement of angles, the following procedure in visual perception was carried out. A circular disc, 38 inches in diameter was mounted on a tripod with the center 47 inches from the floor (approximately eye level for the subject). A pointer 20 inches long and 1 inch wide was pivoted in the center of the disc. The disc was painted dull black, the pointer white. The subject was seated approximately 6 feet from the visual target in the darkened anechoic chamber. The tester moved the pointer until the subject judged the angle formed between the pointer and a point at 9 o'clock on the disc to be vertical (90°) or horizontal (180°). For vertical judgements, responses were obtained with the pointer moving from the left and from the right. The back of the disc was calibrated in 1 steps. After each judgement, the error in degrees to the right or to the left of the test angle was recorded.

Table 2 shows the error in degrees for each subject's judgement of vertical and horizontal angles. Both subjects performed within the normal range.

Fig. 27

Fig. 28.

Fig. 27 Percent correct localization of variable speaker as a function of target azimuth.

Fig. 28 Same data as Fig. 27 but result averaged across fields.

right or identical with the target azimuth of the 400 Hz signal. If for example the 400 Hz signal was placed at an azimuth of 45° in the right field and the subject felt that the 800 Hz signal was at an azimuth of 45° in the left field then he would respond "same". If he felt that the azimuth of the 800 Hz signal was less than 45° he would respond "right" indicating that the apparent location of the variable speaker was to the right of an imaginary reference point or "target azimuth" at 45° in the left field. If he thought that the azimuth of the 800 Hz tone was greater than 45° he would respond "left" etc. Before actual testing commenced the variable speaker was set to the same azimuth as the fixed speaker and the subject was permitted to listen to the alternating sounds as long as he wished in order to establish the "target" azimuth for the variable speaker. During each experimental run the azimuth of the variable speaker was randomly varied in steps of 5°. Testing proceeded until azimuths were identified that the subject consistently judged (3 consecutive trials) as either right or left of the target azimuth or until all azimuths in the variable field had been presented. The former procedure could be employed with C, but the latter was necessary with E.

Fig. 27 presents data for fixed azimuths of 0° and 15°, 45° and 75°. In each auditory field the datum point at each azimuth is the percentage of trials on which each subject correctly responded "right" when the variable speaker was to the right of the target azimuth, and "left" when the variable speaker was to the left of the target azimuth. Judgements for signals presented at plus or minus 5° from the target azimuth however were excluded from the analysis.

As seen in Fig. 27 subject C scored 100% correct when the fixed loud

V CRITICAL ON TIME

The curious manner in which the apparent location of the sound moved from E's left to right ear in the intracranial localization experiment suggested a critical relation between loudness and duration on the right ear. Efforts to pursue this possible relationship by loudness balance technique were unsuccessful. Reliable data could not be obtained. E commented that the signals did not sound the same in the two ears, but he was unable to qualify this dissimilarity further. All efforts to obtain reliable points of balance between the two ears failed.

We reasoned, however, that the presence of such a critical relationship should be manifest in the threshold-duration function. We set out, therefore, to study the relationship between threshold SPL and signal duration. Thresholds were measured by the method of adjustment. The subject listened to a train of tone bursts and adjusted a 2-dB step attenuator to the lowest level at which he could just hear the signal train. Off time between successive signals was held constant at 2000 msec. On-time was varied over the range from 20 to 1000 msec. The rise-decay time for each signal was 5 msec.

Fig. 29 shows results for both subjects at 500, 1000, 2000 and 4000 Hz. For subject C on-duration had little effect on the threshold SPL. In marked contrast, however, subject E's threshold-duration functions were clearly related to signal duration. The effect was slight but apparent on the left ear and quite marked on the right ear. At 500 Hz, for example threshold SPL increased more than 60 dB as signal duration was decreased from 1000 to 20 msec. Similar effects were noted at 1000 and 2000 Hz. At 4000 Hz both ears clearly demonstrated the phenomenon, but the effect was still greater in the right ear.

We believe that the data shown in Fig. 29 help to explain a number of the aberrant phenomena observed in E's performance. The fact that threshold is so critically dependent on signal duration, especially in E's right ear, helps to explain the discrepancy between conventional manual and Békésy thresholds on this ear (see Fig. 8). For conventional manual audiometry signal duration was probably well in excess of 1000 msec. For Békésy audiometry, however, signal duration was only 200 msec. There may have been, in addition, an interaction between the relatively short on-time and the equally short off-time in the Békésy signal, a possibility which was not explored in the present investigation.

It is of further interest to note in Fig. 29, that E's threshold SPL's for the 1000 msec duration are considerably lower than the threshold SPL's

We found an absolute error of approximately 1° to the left for all responses. Apparently E could judge position in visual space as accurately as C.

Summary

On tasks involving both absolute and relative sound localization subject E showed marked impairment. Errors were both large and unreliable from trial to trial. Pure tone, click and sawtooth noise signals all reflected the deficit. In the case of absolute localization there was a tendency for both directional and non-directional errors to be greater in the right auditory field but on relative localization little asymmetry could be discerned.

Of particular significance was the patient's report, confirmed by studies of intracranial localization, that for signal durations greater than 100 msec the apparent location of the sound moved over a rather wide arc generally from left to right between signal onset and termination.

The curious manner in which the apparent location of the sound moved from E's left to right ear in the intracranial localization experiment suggested a critical relation between loudness and duration on the right ear. We tried to pursue this possible relationship by loudness balance techniques but were unsuccessful. Reliable data could not be obtained. He commented that the signals did not sound the same in the two ears, but he was unable to quantify this dissimilarity further. All efforts to obtain reliable points of balance between the two ears failed.

We reasoned, however, that the presence of such a critical relationship should be manifest in the threshold-duration function. We set out, therefore, to study the relationship between threshold SPL and signal duration. Thresholds were measured by the method of adjustment. The subject listened to a train of tone bursts and adjusted a 2-dB step attenuator to the lowest level at which he could just hear the signal train. Off-time between successive signals was held constant at 2000 msec. On-time was varied over the range from 20 to 1000 msec. The rise-decay time for each signal was 5 msec.

Fig. 29 shows results for both subjects at 500, 1000, 2000 and 4000 Hz. For subject C on-duration had little effect on the threshold SPL. In marked contrast, however, subject E's threshold-duration functions were clearly related to signal duration. The effect was slight but apparent on the left ear and quite marked on the right ear. At 500 Hz, for example, threshold SPL increased more than 60 dB as signal duration was decreased from 1000 to 20 msec. Similar effects were noted at 1000 and 2000 Hz. At 4000 Hz both ears clearly demonstrated the phenomenon, but the effect was still greater in the right ear.

We believe that the data shown in Fig. 29 help to explain a number of the aberrant phenomena observed in E's performance. The fact that threshold is so critically dependent on signal duration, especially in E's right ear, helps to explain the discrepancy between conventional manual and Békésy thresholds on this ear (see Fig. 6). For conventional manual audiometry signal duration was probably well in excess of 1000 msec. For Békésy audiometry, however, signal duration was only 200 msec. There may have been, in addition, an interaction between the relatively short on-time and the equally short off-time in the Békésy signal, a possibility which was not explored in the present investigation.

It is of further interest to note in Fig. 29 that E's threshold SPLs for the 1000 msec duration are considerably lower than the threshold SPLs

Fig 29 Threshold SPL as a function of signal duration: (A) 500 Hz, (B) 1000 Hz, (C) 2000 Hz, (D) 4000 Hz.

obtained by conventional manual audiometry. The discrepancy is especially large at 4000 Hz where the conventional audiometric threshold SPL was more than 90 dB (Fig. 6) while the threshold SPL obtained by the method of adjustment (Fig. 20 D) at 1000 msec was only 36 dB SPL. An even lower threshold SPL was obtained at the 100 msec duration.

At first glance these discrepancies would appear to indicate nothing more than extreme instability of E's auditory thresholds. We have been impressed, however, by the fact that as this experiment progressed, F's apparently extreme instability became ever more susceptible of rational explanation. In the case of thresholds, results were critically affected by very small changes in signal parameters, but as these parameters were more rigidly specified, quite repeatable results could be obtained.

A further case in point relates to sound localization. Initial results obtained for both absolute and relative localization seemed little short of chaotic. Results were superficially quite unreliable. A source at the same azimuth might be variously localized almost anywhere in auditory space.

Fig. 30. Hypothetical relative intensity growth function for E's two ears, based on the threshold data of Fig. 29 B.

on repeated trials. At times E's responses seemed little more than chance guesses. The data of Fig. 29 suggest, however, a rational explanation for this confusion. We may reason from these duration functions that the relative intensity of supra-threshold signals is also critically affected by signal duration. Fig. 30 illustrates how relative intensity might be expected to change as a function of duration in E's two ears. The data are taken from Fig. 29 B (1000 Hz) and are replotted as intensities relative to the level of the signal on the left ear at a duration of 1000 msec. Differences in threshold SPL as a function of duration are assumed to reflect differences in relative intensity of a suprathreshold signal as a function of on-time. If this transposition is valid we can see that a sound source anywhere in E's auditory space must necessarily produce a much larger initial effect on his left ear than on his right ear. The effect is so large (more than 50 dB at 20 msec) that it will effectively overcome subtle differences in phase, interaural intensity or arrival time. Thus any sound, at any position, must, at its onset, be referred to the left ear. As the sound continues, however, the right ear makes an ever increasing contribution, and the sound image moves from left to right. After the sound has been on for about one second, the right ear is contributing almost as much as the left and the sound has moved as far to the right as it can go.

If under these circumstances, the subject is placed in a relatively unstructured situation in which a sound is presented for 10 sec, and he is instructed to report where he hears it, confusion and unreliability are quite understandable. At times he may report the apparent location at its onset, at times at its termination, at times in the middle of its duration. At other times the movement may be so confusing that no stable location can be assigned to it.

When the experimental task was more rigidly structured, however, as in

Fig. 25 Threshold SPL as a function of signal duration: (A) 500 Hz, (B) 1000 Hz, (C) 2000 Hz, (D) 4000 Hz.

obtained by conventional manual audiometry. The discrepancy is especially large at 4000 Hz where the conventional audiometric threshold SPL was more than 90 dB (Fig. 5) while the threshold SPL obtained by the method of adjustment (Fig. 29 D) at 1000 msec was only 30 dB SPL. An even lower threshold SPL was obtained at the 100 msec duration.

At first glance these discrepancies would appear to indicate nothing more than extreme instability of E's auditory thresholds. We have been impressed, however, by the fact that as this experiment progressed E's apparently extreme instability became ever more susceptible of rational explanation. In the case of thresholds, results were critically affected by very small changes in signal parameters, but as these parameters were more rigidly specified, quite repeatable results could be obtained.

A further case in point relates to sound localization. Initial results obtained for both absolute and relative localization seemed little short of chaotic. Results were superficially quite unreliable. A source at the same azimuth might be variously localized almost anywhere in auditory space.

VI AVERAGED ELECTROENCEPHALIC RESPONSE

The averaged electroencephalic response (AER) to auditory signals was studied by standard computer technique. EEG electrodes were affixed to the scalp at the vertex and at either the right or the left mastoid process. Electrodes fed an FM telemetry transmitter attached to the subject's back. The telemetered EEG was received by an FM tuner demodulated, amplified, and fed to an averaging computer (Memotron CAT 1000). The band pass of the EEG signal was 0.2 Hz to 12 Hz.

Auditory signals were delivered monaurally via earphone (Telephonic, TDH-39) at 80 dB SPL. Both pure-tone and click signals were employed. Tone bursts of 1000 Hz had durations of 200 msec, and rise-decay times of 15 msec. Click duration was 1 msec. For both tone bursts and clicks, the interval between successive signals was 2 sec. The computer sampled EEG activity over a 512 msec period following signal onset. One hundred samples were averaged to define each AER. Each ear was tested under two conditions of electrode placement, either vertex-right mastoid, or vertex-left mastoid.

Fig. 31 shows results for 1000 Hz tones. Subject C showed well-defined AERs under all four experimental conditions. Latencies of the three principal deflections λ , P and λ' were 100, 170 and 275 msec respectively. Subject E, however, failed to show clearly-defined AERs under any test conditions. Similar results were obtained at 500 Hz. Subject C showed well-defined responses, but subject E showed none. Under questioning E reported hearing the pure-tone signals on both ears. In addition, when asked to push a response button every time he heard a tone, E scored 100% on both ears. Yet electroencephalic responses could not be demonstrated.

Fig. 32 shows results for clicks. Again C showed well-defined AERs but E showed very little response. On E's left ear there was a small but consistent positive deflection at a latency of approximately 125-150 msec. On the right ear, however, there was no discernable pattern.

For control purposes AERs were obtained in response to flashes of bright light (General Radio, Stroboscope). Responses to 50 successive flashes were averaged. Fig. 33 shows the results. Both C and E gave clearly defined AERs. E's responses were, in fact, somewhat better defined than C's.

In further exploration with E, signal intensity, signal frequency, repetition rate and computer sampling period were all varied in an effort to

the intracranial localization experiment F's responses, while still somewhat confused became much more understandable. By and large signals presented in phase and at equal intensity to the two ears tended to be heard first in the left ear then to move toward the right ear.

In effect the critical duration phenomenon renders any localization data ambiguous. E's judgements of apparent localization based on 10 sec signals are confounded by the on time effect to an unknown degree.

VI. AVERAGED ELECTROENCEPHALIC RESPONSE

The averaged electroencephalic response (AER) to auditory signals was studied by standard computer technique. EEG electrodes were affixed to the scalp at the vertex and at either the right or the left mastoid process. Electrodes fed an FM telemetry transmitter attached to the subject's back. The telemetered EEG was received by an FM tuner, demodulated, amplified, and fed to an averaging computer (Minemotron CAT 1000). The band pass of the EEG signal was 0.3 Hz to 12 Hz.

Auditory signals were delivered monaurally via earphone (Telephonic, TDH-39) at 80 dB SPL. Both pure-tone and click signals were employed. Tone bursts of 1000 Hz had durations of 200 msec, and rise-decay times of 20 msec. Click duration was 1 msec. For both tone bursts and clicks, the interval between successive signals was 2 sec. The computer sampled EEG activity over a 512 msec period following signal onset. One hundred samples were averaged to define each AER. Each ear was tested under two conditions of electrode placement, either vertex-right mastoid, or vertex left mastoid.

Fig. 31 shows results for 1000 Hz tones. Subject C showed well-defined AERs under all four experimental conditions. Latencies of the three principal deflections λ_1 , P and λ_2 were 100, 170 and 275 msec respectively. Subject E, however, failed to show clearly-defined AERs under any test conditions. Similar results were obtained at 500 Hz. Subject C showed well-defined responses, but subject E showed none. Under questioning E reported hearing the pure-tone signals on both ears. In addition, when asked to push a response button every time he heard a tone, E scored 100% on both ears. Yet electroencephalic responses could not be demonstrated.

Fig. 32 shows results for clicks. Again C showed well-defined AERs but E showed very little response. On E's left ear there was a small but consistent positive deflection at a latency of approximately 125-150 msec. On the right ear however there was no discernable pattern.

For control purposes AERs were obtained in response to flashes of bright light (General Radio, Stroboscave). Responses to 50 successive flashes were averaged. Fig. 33 shows the results. Both C and E gave clearly defined AERs. E's responses were in fact, somewhat better defined than C's.

In further exploration with E, signal intensity, signal frequency, repetition rate and computer sampling period were all varied in an effort to

Fig. 31

Fig. 31 Computer averaged electroencephalic responses (AER) to 100 successive tone bursts. The frequency was 1000 Hz and the interval between tones was 2 sec.

Fig. 32.

Fig. 33.

find some combination of parameters that might elicit an AER. All efforts were fruitless. It should be noted however that we did not explore the "early" response in the range from 0-60 msec (Goldstein and Rodman, 1967).

In any event the failure to obtain "slow" responses (Davis and Zerlin, 1968) in the 0-500 msec range is of some interest. We have here a situation in which the patient "hears" the sounds, attends closely by pushing a button every time he "hears" the sound, and yet fails to demonstrate an AER in response to sound.

VII DISCUSSION

Little difficulty is encountered in anatomic localization of the lesions in this case. Although the patient had mixed dominance the initial presentation with aphasia, right sided sensory symptoms and right facial paresis indicated a left cerebral hemisphere lesion. This conclusion was confirmed by the EEC brain scan and arteriographic studies. The second phase of the illness, although not associated with further clinically localizing or lateralizing phenomena, was clearly related to a right cerebral hemisphere lesion again on the basis of EEC brain scan and arteriographic data. It is our contention that these bilaterally placed cerebral lesions were directly responsible for the patient's hearing loss. The audiological data presented support this thesis. Nonetheless, the mere coincidental existence of cerebral lesions and hearing loss does not in itself prove causality; exclusion of other possible responsible sites being essential for the establishment of such a relationship.

The tuning fork tests and bone conduction audiograms proved the hearing loss to be of the sensori neural type. The data obtained from speech audiometry further narrowed the range of anatomic considerations by pointing away from cochlear disease. In order to establish a causal relationship between the cerebral lesions and the hearing loss, only the further possibilities of auditory nerve and brainstem disease need to be excluded. The abrupt onset of bilateral hearing loss, the absence of vertigo and tinnitus, the lack of exposure to ototoxic agents and acoustic trauma, the normal GSR, the negative skull X rays and the normal caloric responses to ice water though certainly not diagnostic when taken each in isolation at least make significant auditory nerve disease highly improbable when considered in toto. This is particularly true in view of the marked disturbance of auditory nerve function which would be required to produce the striking severity of loss exhibited by this patient at the time of his second admission. Since the brainstem contains a closely packed mass of neural elements, which, in addition to audition are intimately concerned with motor sensory oculomotor vestibular postural, bulbar reflex and autonomic functions, one would certainly expect disturbances in at least some of these functions, were the patient's deafness to be caused by disruption of the brainstem auditory pathways. This concept is illustrated by the five patients with brainstem disease and audiology abnormalities reported by Fichel, Hedgecock and Williams (1966). All of those patients had rather striking symptoms or signs specifically referable to the brainstem. Such was not the case with our patient. The minor abnormalities found in motor

sensory and reflex functions were, as has been pointed out, referable to cerebral hemisphere disease. Thus, a brainstem cause of hearing loss is also extremely improbable.

The patient's clinical course was characteristic of cerebral infarction as were the evolutionary changes seen on EEG (Kiloh and Osselton, 1961) and brain scan (Rhoton, Kinkerfuss, Lilly and Ter-Pagossian, 1966; Monnier, Pircher and Hevman, 1967). The arteriographic demonstration of bilateral occlusions of the distal middle cerebral branches gave graphic evidence of the lesions responsible for such infarction. However the etiology remains obscure. The patient had a wide pulse pressure with systolic hypertension, probably due to thyrotoxicosis rather than to one of the hypertensive vascular diseases. Detailed anamnestic, physical and laboratory investigation failed to disclose any evidence of diabetes mellitus, syphilis, migraine, a hypercoagulable state, cardiac disease, inflammatory angiopathy, blood dyscrasia, congenital aneurysm or other vascular anomalies. Indeed, the only laboratory abnormalities detected, outside of those directly related to thyroid function, were some minor non-specific changes in serum protein electrophoresis and immunoglobulin patterns and a small elevation in serum viscosity. The latter is frequently found following cerebral infarction and is also, therefore, not of diagnostic aid in this case (Eisenberg, 1966). Thus, none of these findings resulted in an etiologic diagnosis. To our knowledge, thyrotoxicosis cannot be directly implicated as a cause of cerebrovascular occlusion except when it is associated with cardiac arrhythmia, mural thrombus formation and embolization. Although no evidence of atrial fibrillation was obtained through five months of in-hospital evaluation, including radial pulse counting four times daily and during sleep during three of these months, this possibility cannot be entirely dismissed from consideration but appears remote. The occurrence of occlusive cerebrovascular disease in young adults is not an uncommon phenomenon (Berlin, Tumarkin and Martin, 1955; Louis and McDowell, 1967). Middle cerebral artery occlusion particularly is common in the younger age group among the 59 cases reviewed by Lascelles and Burrows (1960): 29 were less than 50 years old, and 10 were less than 30 years old. At the present time then, no etiologic diagnosis is possible in our patient.

We conclude from these data that the patient whose case is here presented experienced, at two different points in time, occlusion of the terminal branches of the middle cerebral artery on each side, resulting in bilateral partial cerebral hemisphere infarction, maximal in the temporal lobes, and producing the clinical picture of cortical deafness.

The evaluation of auditory function in the present patient revealed a complex configuration of assets and deficits. Although auditory sensitivity as measured by conventional manual audiometry was grossly unimpaired, final threshold—particularly on the patient's right ear—were critically dependent on perceptible signal parameters, especially on duration. This factor appeared to underlie both threshold instability and impaired sound

localization. Its rigid control in the further study of patients with temporal lobe lesions, is urgently recommended.

In spite of the bilateral configuration of this patient's lesions, performance on tasks involving speech intelligibility and loudness discrimination was measurably poorer on the right ear. This result is consistent with previous demonstrations (Bocca *et al.*, 1955; Bocca 1958; Jerger 1960; B. Jerger 1964) that elementary auditory perceptual tasks reflect the lateralization of temporal lobe damage rather than impairment in the hemisphere dominant for speech. Left temporal lobe damage produces poorer performance on the right ear and right temporal lobe damage produces poorer performance on the left ear. Indeed, the very fact of ear differences argues that these simple tasks probe aspects of auditory perception with dual representation in the two hemispheres. They must in effect tap performance at a level well below the language function of the dominant hemisphere. In the present patient these ear differences merely suggest greater damage to the auditory areas of the left temporal lobe.

Surprisingly, however, performance on tasks involving temporal ordering of auditory events failed to show these ear differences. Both ears reflected about the same degree of impairment.

This set of findings is consistent with Efron's (1963) argument that temporal analysis is performed in the dominant temporal lobe. According to Efron's hypothesis the temporal analysis of sequence is a relatively high level perceptual function and is localized in the hemisphere dominant for speech. On the basis of this argument it is entirely predictable that our patient should show equivalent impairment in temporal ordering no matter which ear is tested.

If temporal ordering were at the same perceptual level as the speech intelligibility and loudness discrimination tasks, then we should have expected to find the same ear differences on temporal order as on the speech and loudness tasks. On the contrary, the experimental findings for temporal order showed no ear differences, a result consistent with the hypothesis that the perception of temporal sequence is, indeed, a function of the dominant hemisphere.

I INTRODUCTION

Reviews of the literature concerned with development of speech in children have provided much information on grammatical, contextual and syntactic aspects (Miller and Smith, 1968) but somewhat less on phonetic aspects (Irwin, 1943, 194 1948 Morley 1965 Simon, 1957) of speech development. Phonetic studies, particularly since the introduction of the Sound Spectrograph in 1946, have clarified certain acoustical characteristics of speech sound (Potter Kopp and Green, 1947 Joos, 1948 Peterson and Barney 1952 Potter and Steinberg, 1950 Peterson, 1950) and these characteristics have been confirmed subsequently by acoustical resonance theory (Dunn, 1950 Stevens and House 1955, 1961 Fant, 1960 Cooper *et al* 1962) Potter and Steinberg (1950) and Peterson and Barney (1952) reported that the vowel formant frequencies of children were about 25% higher than those of the adult male and 20% higher than those of the adult female. The rapid anatomical, physiological and psychological development in childhood would, of course predict that these acoustical features of the speech sounds or phonemes of children could not remain stable over any long period of time. However there is a scarcity of acoustical studies concerned with the development of speech sounds or phonemes in children (Okamura, 1966).

The present investigation was designed to clarify the way in which speech sounds or phonemes develop in normal children after the initial stages of language acquisition. Measurement of the formant frequencies that characterize certain vowels in a sentence spoken by children at different ages would provide information on the formant shifts that occur with age. Furthermore calculation of the variability of such formants in samples of repetitions of the sentences would provide information on the accuracy with which children uttered such vowels. Measurement of the vocal fundamental frequency would provide information on changes with age and another kind of measurement namely of certain interphonemic time intervals, would provide both mean and variability for at least one aspect of consonant development. Finally to ascertain what relation might exist between variability of vowel formant and the intelligibility of vowels, certain listening tests were carried out.

I INTRODUCTION

Reviews of the literature concerned with development of speech in children have provided much information on grammatical, contextual and syntactic aspects (Miller and Smith, 1966) but somewhat less on phonetic aspects (Irwin, 1947, 1948, 1948 Morley 1965; Simon, 1953) of speech development. Phonetic studies, particularly since the introduction of the Sound Spectrograph in 1946, have clarified certain acoustical characteristics of speech sounds (Titterton and Green, 1947; Joss, 1948; Peterson and Barney 1952; Potter and Steinberg, 1950; Peterson, 1959) and these characteristics have been confirmed subsequently by acoustical resonance theory (Dunn, 1950; Steven and House 1955, 1961; Fant, 1960; Cooper *et al* 1952). Potter and Steinberg (1950) and Peterson and Barney (1952) reported that the vowel formant frequencies of children were about 25% higher than those of the adult male and 20% higher than those of the adult female. The rapid anatomical, physiological and psychological development in childhood would, of course, predict that these acoustical features of the speech sounds or phonemes of children could not remain stable over any long period of time. However, there is a scarcity of acoustical studies concerned with the development of speech sounds or phonemes in children (Okamura 1966).

The present investigation was designed to clarify the way in which speech sounds or phonemes develop in normal children after the initial stages of language acquisition. Measurement of the formant frequencies that characterize certain vowels in a sentence spoken by children at different ages would provide information on the formant shifts that occur with age. Furthermore, calculation of the variability of such formants in samples of repetition of the sentences would provide information on the accuracy with which children uttered such vowels. Measurement of the vocal fundamental frequency would provide information on changes with age and another kind of measurement, namely of certain interphonemic time intervals, would provide both mean and variability for at least one aspect of consonant development. Finally, to ascertain what relation might exist between variability of vowel formant and the intelligibility of vowels, certain listening tests were carried out.

Subjects

Eighty four subjects, ranging in age from 3 to 13 years, and also adults, served as talkers. Subjects older than 10 years were divided into two groups according to sex. Each age or age-sex group contained five or six subjects. All subjects were from the Greater St. Louis area.

Test material

Two sentences, "He has a blue pen" and "I am tall" which are easy to pronounce and available in the daily conversation of children were selected as the test sentences.

Six vowels, representative of a variety of tongue positions in vowel articulation were selected for spectrographic analysis, in order from the sentences above: [i], [æ], [u], [ɛ], [a], [o]. (The sound of [a] not normally found in most American dialects, was taken from the first portion of the diphthong [ai] in the word "I".) In addition the words "blue" "pen" and "tall" were used for the measurement of certain temporal features in the words.

Recording procedures

Tape recordings of the test sentences were made in a room where the signal to-noise ratio was 32 dB or better. Each sentence was spoken by each subject on five different occasions, separated by only a few minutes. Children over 7 years of age read the sentences from a card, while younger subjects repeated them after a native American speaker (JH) who speaks with a general Eastern dialect. Speech samples at approximately 70 dB SL (re 0.0002 dyne/cm²) were picked up by a condenser microphone at a distance of about 0.5 meter and were recorded on tape by an Ampex (Model 300) tape recorder. Background and internal noise was further reduced by a 300-Hz high pass filter whose low frequency response fell at 12 dB per octave.

III VOWEL FORMANT FREQUENCIES

Method

A Sound Spectrum Analyzer (Ray Sona-Graph Model 8061A) was used for the acoustical analysis of reproduced speech sounds. Steady-state portions of the vowels were identified from both wide-band and narrow band spectrograms. The first and second formant frequencies for each vowel on each repetition of each subject were estimated from the spectrum envelopes drawn on expanded narrow-band sections (0-1000 Hz) (Fig. 1).

In each age group, the mean formant frequencies and between subject standard deviations were calculated from the mean values of each subject, while intra-subject standard deviations were calculated as the square root of the mean value of the individual variance within each age group.

These intra-subject standard deviations of the distribution of five repetitions within each age group were used as a measure of variability or the inverse of precision, of articulation and were calculated either in absolute terms or in terms of ratios to the individual means.

Since the present study focuses on measures of variability associated with talker repetitions, age and different vowels, some information about error of measurement of formant frequencies through visual inspection of spectrogram sections is required. Several previous reports have addressed themselves to this problem. With age as a principal variable, Potter and Steinberg (1950) reported no correlation between the fundamental frequency and formant frequency for their three groups of adult males, adult females, and children. More directly related to the present report was their further finding that repeated utterances by a number of talkers showed a standard deviation of 20-40 Hz for the first formant, and 40-70 Hz for the second formant. Corresponding measurements for children (8 years) yielded values about twice as large. Distributions of single utterances from a large number of talkers had standard deviations two or three times as large. Peterson and Barney (1952) reported that the standard deviation for the first formant of a repeated vowel (/i/) by adult females was 15.3 Hz. They did not attribute this value to a specific source but suggested that it represented intra-subject variability that is, over several trials by the same talker and they stated further that this value was not easily interpretable in comparing one talker with another. Finally and more specifically concerned with error of spectrographic measurement, Lindblom (1962) studied the accuracy with which formant frequencies could be estimated from spectrograms of synthesized vowels. He compared the values read by five experienced investigators and obtained a between-reader standard deviation of 40 Hz for adult male voice pitch, that is, a value about one-fourth the fundamental frequency.

Fig. 1. Spectrogram of a child's rendition of "H ha blue pen a i am t l". Wide-band spectrogram is shown at the top, and narrow-band at the center. At the bottom are seen the sections with indicated points in time which show the spectral distribution of the vowel is up to 4 kHz.

We cannot find any study on intra reader variability that is, the reliability with which a single investigator will draw his spectrum envelopes and interpolate the peak values on successive readings of the same recorded sample. Accordingly one of us (S. E.) estimated from sections the first and second formants of six different vowels spoken by a 6-year-old child and by an adult male. Five sets of narrow-band sections (0-4 kHz) were recorded from the spectrogram and he then made his estimates on different occasions and in haphazard order. The typical standard deviation within any set of five was about 10 Hz, a value considerably lower than any that will

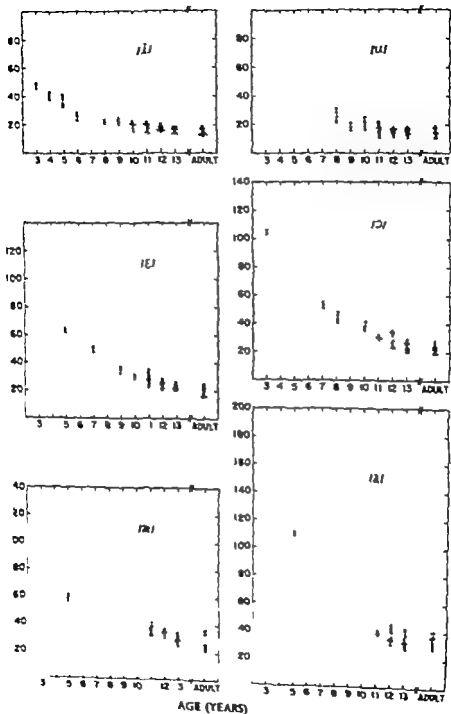

Fig. 3. Inter-subject reliability of first formant for all vowel functions of age. Each point represents the standard deviation in Hz for each subject used in the experiment. The sex of 10 females is indicated by filled circles, while males are indicated by open circles.

Fig. 2 Mean formant frequencies for combined age groups as shown in the key. Each point represents the combination of Formant 1 and Formant 2 for each of the six vowels. The different symbols together with the lines that join them represent the different ages. The broken circles are drawn around all points for a given vowel.

the first formant frequency (first column, upper half) with the exception of the first formant frequency for the vowel [a]. This was especially clear during the period from 3 to 5 years. Formant frequencies of 12-year-old girls were close to those of adult females, while 13-year-old boys had higher formant frequencies than did adult males. Formant frequencies of adults showed almost the same values as those found in the literature (Peterson and Barney, 1952; Fairbanks and Crubb, 1951; Potter and Steinberg, 1950).

In order to assess the dependence of formant frequencies on age, values were averaged for the following age groups: 3 and 4 years, 7 and 8 years, 11 and 12 year-old girls, 13 year-old girls, and male and female adults. The results are shown in Fig. 2 as the familiar F_1 - F_2 plot with the vowels of each age group connected to form a "vowel triangle."

Here, the gradual but marked decrease in second formant frequencies, as contrasted with the more stable first formant frequencies, is shown. Another feature that stands out is that the first formant frequency for [a] appears to be independent of age.

Between subject standard deviations. Standard deviations of the distribution of individual subject means (second column) within each age group

Fig. 4. Intra-subject variability of second formant. Each point represents the standard deviation in Hz of each subject used in the experiment. Above the age of 10, females are indicated by filled circles, while males are indicated by open circles.

Fig. 5. Intra-subject variability of First Formant typical of the different age groups as a function of age. Each point represents the square root of the average variance for the children in each age group. The different symbols and the different lines connecting them for each of the vowels are identified in the key.

for the first and second formant frequencies varied between 40 and 450 Hz. Age does not appear to be a factor in between-subject standard deviations for either the first or second-formant frequency. In other words, individual's mean formant frequencies do not appear to become more like each other as the individuals get older.

Intra-subject standard deviations. The five sentence repetitions permitted calculation of intra-subject standard deviation for first and second-formant frequencies, which are shown in Figs. 3 and 4 respectively. Each point represents a standard deviation for each subject. The filled points show data for female subjects above the age of ten.

The variability of first-formant frequencies was higher for middle vowels than for high-front and high-back vowels, but for all vowels the variability decreases with age, reaching a minimum value which corresponds to that for adults, at about age 11 to 13. While there is no clear dependence of variability of second-formant frequency on particular vowels, the dependence on age was the same.

Summaries of average variability typical of each age group for the first and second formant frequencies are shown in Figs. 5 and 6 respectively.

The differences in variability of first formant frequencies among the

Fig. 6. Intra subject variability in Formant 2 typical of the different age groups as a function of age. In this figure each \square represents the square root of the average variance for the children in each age group. The different symbols and the different lines connecting them for each of the six vowels are identified in Table V.

vowels are clear here. Variability of [a] is the highest of all vowels while the variabilities of [i] and [u] are the lowest. The variability of first formant frequencies is 140 Hz for [a], 55 Hz for [i] and [u], and 100 Hz for [e], [æ], and [ɔ] at the age of 3. At 13 years, however, it is 30 Hz for [a], 15 Hz for [i] and [u], and 21–20 Hz in [e], [æ], and [ɔ], the same values as those of an adult. The variability of second formant frequencies is approximately the same for all vowels. The variability of second formant frequencies ranged from 120 to 150 Hz at three years and 30 to 57 Hz at thirteen years, reaching adult values.

Ratio of intra subject standard deviation to mean value. It is obvious from Fig. 5 that the intra subject variability of first formant for [a] is higher than that for either [i] or [u] but then so is the mean first formant frequency. Perhaps variability should be reckoned not as an absolute value but as a fraction of the mean around which the values vary. Accordingly we show the same data in Fig. 6, but the ordinate describing variability is the ratio of the standard deviation in Hz to the child's own mean first formant frequency. Indeed, the differences among the vowels are less distinct. The decrease with age remains as before.

Fig. 6 showed a fair homogeneity of the absolute variability of the

Fig. 7 Simplified of first formant data shown in Fig. 5, but with the variability expressed on the y-axis as the ratio of the standard deviation to the mean formant frequency.

second formant for different vowels in absolute terms, but Fig. 8 shows how the relative variabilities separate according to the mean second-formant frequencies.

The relative variabilities for the first formant for the 3-year-olds are still highest for [a] (0.171) and lowest for [i] and [u] (0.096, 0.11). By the age of 11 or 12, however, the ratios are similar for all vowels (0.09 or 0.1) and they remain the same as they descend to the adult value of 0.03 to 0.05. For the second formant the s.d./mean ratio is lowest for [i] and higher for [a], [e], and [u], and this finding is independent of age.

Discussion

Acoustical phonetics characterizes phonemes or speech sounds in articulatory terms by places or gestures of the tongue and in acoustic terms by formant and transitions. In the past, studies on vowel formant frequencies have been required to clarify some acoustic features of speech sounds. It has been recognized that the vowel formants represent the acoustic resonant properties of vocal tract as shaped in articulation by the tongue (Chaffin, Kopp and Green, 1917; Jones, 1918; Peterson and Barney, 1952).

Fig 6 Intra subject variability in Formant 2 typical of the different age group as a function of age in this figure each point represent the square root of the error variance for the children in each age group. The different symbols and the different lines connecting them for each of the six vowel are identified in the key

vowels are clear here. Variability of [a] is the highest of all vowels while the variabilities of [i] and [u] are the lowest. The variability of first formant frequencies is 170 Hz for [a], 55 Hz for [i] and [u] and 100 Hz for [e], [ɔ] and [ɒ] at the age of 3. At 13 years, however, it is 30 Hz for [a], 15 Hz for [i] and [u] and 21-25 Hz in [e], [ɔ] and [ɒ], the same values as those of an adult. The variability of second formant frequencies is approximately the same for all vowels. The variability of second formant frequencies ranged from 120 to 150 Hz at three years and 35 to 57 Hz at thirteen years, reaching adult values.

Ratio of intra subject standard deviation to mean value. It is obvious from Fig 5 that the intra subject variability of first formant for [a] is higher than that for either [i] or [u], but then so is the mean formant frequency. Perhaps variability should be reckoned not as an absolute value but as a fraction of the mean around which the values vary. Accordingly, we show the same data in Fig 4, but the ordinate describing variability is the ratio of the standard deviation in Hz to the child's own mean first formant frequency. Indeed the differences among the vowels are less distinct. The decrease with age remains as before.

Fig 11 showed a fair homogeneity of the absolute variability of the

unit length section of the back cavity is larger than the shift caused by a removal of a section of the same length in the middle of the front cavity.

F_1 of the vowels [e], [i], and [ɪ] is almost completely determined by the back cavity volume and the narrowest section of the mouth cavity. In the vowels [u], [o], and [ɔ] is somewhat more dependent on the front cavity constrictor section. The contribution to F_1 of [u] from the back cavity volume is somewhat larger than that from the front cavity.

The second formant. Only in the case of the vowel [i] was the mouth cavity with associated orifices found to be the essential determinant of F_2 . F_2 of [i] is clearly a half wavelength resonance of the back cavity. There is a similar but not at all so apparent tendency of F_2 of [e] to be influenced more by the back than by the front cavity. The second formant of the back vowels [a], [ɒ], and [ɑ] is somewhat more dependent on the front cavity than on the back cavity. Providing the cavity volume changes are introduced on a constant percentage basis, this tendency is apparent, but if the volume changes are performed by means of a constant length reduction there is found an equal dependency of F_2 on the two cavities for [u] and also for [ɑ]. In the case of [u], F_2 is dependent much more on the relative dimensions of the tongue pass than on the lip section. These two parts of the compound resonator system have about the same effect on F_2 of both [ɑ] and [o]. The lip section is of practically no importance for F_2 of [i] and does not have a very marked influence of [e] either" (Fant, 1960 p. 121).

There are only a few studies of vowel formant frequency of children (Potter and Steinberg, 1940; Peterson and Barney, 1952) especially on the development of formant frequencies (Potter and Peterson, 1948; Okamura, 1968). What is known is that formant frequencies of eight year old children are about 25% higher than that of adult males and 20% higher than that of adult females.

Okamura (1968) reported, in his study on formant contractions and differentiation of vowel area in two-formant space, that Japanese vowel formant frequencies can be differentiated from each other by the age of nine.

Needles to say the vocal tract of a child is smaller in size than that of an adult but we cannot easily assume that the formants have higher frequencies in proportion to the size of the vocal tract with age as a whole because different parts of the vocal tract presumably change at different rates.

In a study on the anatomical development of voice and speech organs in children Negu (1910) pointed out that the larynx develops most rapidly between the ages of 3 and 5 years, and then development of the larynx becomes more gradual with age until puberty is reached.

Our results on formant frequencies can be summarized as follows:

(a) There is a clear decrease of first and second formant frequencies between ages 3 and 5 years.

(b) Generally the decrease of the second-formant frequency is greater than that of the first formant frequency.

Fig. 8. Plotting of second formant d_t shown in Fig. 6, but with the variability expressed on the ordinate as the ratio of the standard deviation to the mean formant frequency.

Peterson, 1951, 1959; Potter and Steinberg, 1950; Stevens and House, 1961). Identification of the vowel is chiefly dependent on the first and the second formants.

One simple notion from the past was that the first formant corresponds to the back cavity and the second formant corresponds to the front cavity of the mouth (Joos, 1948). However, it has also been reported that the formants generated by different talkers speaking the same vowel have different frequencies and that formants generated in producing different vowels may have the same frequency. A theory based on absolute values for vowel formant frequency has great difficulty (Stevens and House, 1963). Various investigators have considered as a basis for this confusion size of vocal tract, dialect and many other factors.

Recent studies of synthesized speech and measurement of the size of vocal tract on X-ray pictures reveals that the first and second formants are not simply acoustic features of front cavity and back cavity in the vocal tract (Fant, 1960). For example:

The first formant. The frequency of the first formant F_1 is generally dependent more on the back cavity volume than on the volume of other cavities. An exception is the vowel [a] where F_1 is affected equally on a percentage basis by a change in the front cavity volume and by a change of the back cavity volume. Since the back cavity of [a] is much shorter than the front cavity, the percentage increase of F_1 due to the removal of a small

unit length section of the back cavity is larger than the shift caused by a removal of a section of the same length in the middle of the front cavity.

"*T*" of the vowels [e], [i], and [ɪ] is almost completely determined by the back cavity volume and the narrowest section of the mouth cavity. In the vowels [u], [o], and [ɔ] is somewhat more dependent on the front cavity constriction section. The contribution to F_2 of [u] from the back cavity volume is somewhat larger than that from the front cavity.

The second formant. Only in the case of the vowel [i] was the mouth cavity with associated orifices found to be the essential determinant of F_2 . F_2 of [i] is clearly a half wavelength resonance of the back cavity. There is a similar but not at all so apparent tendency of F_2 of [e] to be influenced more by the back than by the front cavity. The second formant of the back vowels [u], [o], and [ɔ] is somewhat more dependent on the front cavity than on the back cavity. Providing the cavity volume changes are introduced on a constant percentage basis, this tendency is apparent but if the volume changes are performed by means of a constant length reduction, there is found an equal dependence of F_2 on the two cavities for [u] and also for [a]. In the case of [u], F_2 is dependent much more on the relative dimensions of the tongue passage than on the lip section. These two parts of the compound resonator system have about the same effect on F_2 of both [a] and [o]. The lip section is of practically no importance for F_2 of [i] and does not have a very marked influence of [e] either" (Fant, 1960 p. 121).

There are only a few studies of vowel formant frequency of children (Potter and Steinberg, 1950 Peterson and Harner 1952) especially on the development of formant frequencies (Potter and Peterson, 1948 Okamura, 1966). What is known is that formant frequencies of eight year old children are about 25% higher than that of adult males and 20% higher than that of adult females.

Okamura (1966) reported, in his study on formant constructions and differentiation of vowel areas in two-formant space that Japanese vowel formant frequencies can be differentiated from each other by the age of nine.

Needless to say the vocal tract of a child is smaller in size than that of an adult but we cannot easily assume that the formants have higher frequencies in proportion to the size of the vocal tract with age as a whole because different parts of the vocal tract presumably change at different rates.

In a study on the anatomical development of voice and speech organ in children, Negu (1919) pointed out that the larynx develops most rapidly between the ages of 3 and 5 years, and then development of the larynx becomes more gradual with age until puberty is reached.

Our results on formant frequencies can be summarized as follows.

There is a clear decrease of first and second formant frequencies between ages 3 and 5 years.

(1) Generally the decrease of the second-formant frequency is greater than that of the first formant frequency.

Fig. 8 Re-plotting of second formant data shown in Fig. 6, but with the variability expressed on the ordinate as the ratio of the standard deviation to the mean formant frequency.

Peterson 1951 1959 Potler and Steinberg 1950 Stevens and House 1961) Identification of the vowel is chiefly dependent on the first and the second formants.

One simple notion from the past was that the first formant corresponds to the back cavity and the second formant corresponds to the front cavity of the mouth (Joos, 1948). However, it has also been reported that the formants generated by different talkers speaking the same vowel have different frequencies and that formants generated in producing different vowels may have the same frequency. A theory based on absolute values for vowel formant frequency has great difficulty (Stevens and House 1963). Various investigators have considered as a basis for this confusion size of vocal tract, dialect and many other factors.

Recent studies of synthesized speech and measurement of the size of vocal tract on X-ray pictures reveals that the first and second formants are not simply acoustic features of front cavity and back cavity in the vocal tract (Fant 1960). For example

"The first formant. The frequency of the first formant F_1 is generally dependent more on the back cavity volume than on the volume of other cavities. An exception is the vowel [a] where F_1 is affected equally on a percentage basis by a change in the front cavity volume and by a change of the back cavity volume. Since the back cavity of [a] is much shorter than the front cavity, the percentage increase of F_1 due to the removal of a small

IV FUNDAMENTAL FREQUENCY

Method

Fundamental frequencies of vowels were estimated from the number of harmonics (up to 4000 Hz) that showed in the narrow band spectrum at the vowel formant sectioning points (Fant, p. 241). Earlier attempts were made to use a greatly expanded frequency scale to read the fundamental frequency directly from the spectrogram. That procedure involves an expanded harmonic line whose thickness offsets any increase in accuracy over the harmonic count.

Results

Data for the fundamental frequencies averaged over all vowels are given in Table 2. The means are based on the 5 repetitions, the 6 vowels, and 5 subjects in each age group. In short, an averaged fundamental typical of owl throughout the sentence. The between-subject s.d. concerns the variation in each age group among the averages of repetitions and vowels. The intra-subject s.d. is the variation among the 5 repetitions, averaged (variance) over all subjects and all vowels. Mean values of fundamental frequencies are shown with between-subject and intra-subject standard deviations in Fig. 9.

Mean values. Fundamental frequency starting from about 200 Hz at 3 years, decreases slightly with age. However the largest decrease of fundamental frequency seems to occur between the ages of 3 and 6 years. Thirteen-year-old boys had an average fundamental frequency of 221.1 Hz, still an octave higher than that of adult males (124.2 Hz). Thirteen-year-old girls, on the other hand, had an average fundamental frequency of 220.8 Hz, not very different from that of adult females (220.9 Hz).

Between-subject standard deviation. Between-subject standard deviation was not dependent on age. It ranged from 20 to 45 Hz. Interestingly, 12-year-old boys showed a standard deviation of 66.1 Hz, which is a higher value than that found for all other age groups.

Intra-subject standard deviation and its relation to mean value. Thirteen-year-old children showed about 40 Hz s.d. yielding a ratio of standard deviation to mean of 0.132. There was a gradual decreasing with age reaching a minimum value (12 Hz, 0.04) at age ten or twelve and after that there was no further decrease in intra-subject standard deviation of fundamental frequency (0.04 to 0.03). This decrease in relative variability is shown in Fig. 10.

(c) The first formant frequency of [a] is independent of age

(d) Between subject standard deviations of formant frequencies are unrelated to age and sex.

From these results and the work of others (e.g. Negus, and Fant) the following conclusions may be drawn

(e) These acoustical results are in accordance with the rapid anatomical development of the vocal tract between the ages of 3 and 5 years.

(f) The development of the front cavity will have a greater influence on changes in formant frequencies than the development of the back cavity.

(g) First formant frequencies of [a] are not so clearly influenced by development of vocal tract but indirectly or mutually influenced by development of front and back cavities, and also other factors (i.e. fundamental frequency etc.)

(h) Variability of formant frequencies for given vowels between subjects is independent of age and sex.

Anatomical factors may not be the only source of these variations, since the development of speech sounds in children is influenced also by psychophysiological development. Further the perception of vowels is dependent not only on formant frequency but also on many other information bearing elements of speech (Peterson 1962). We should not expect therefore to understand the development of vowel formant frequency in children on the basis of the anatomical development of vocal tract alone.

IV. FUNDAMENTAL FREQUENCY

Method

Fundamental frequencies of vowels were estimated from the number of harmonics (up to 4000 Hz) that showed in the narrow-band spectrum at the vowel formant sectioning points (Fant, p. 241). Earlier attempts were made to use a greatly expanded frequency scale to read the fundamental frequency directly from the spectrogram. That procedure involves an expanded harmonic line whose thickness offsets any increase in accuracy over the harmonic count.

Results

Data for the fundamental frequencies averaged over all vowels are given in Table 2. The means are based on the 5 repetitions, the 6 vowels, and 5 subjects in each age group. In short, an averaged fundamental typical of vowels throughout the sentence. The between-subject s.d. concerns the variation in each age group among the averages of repetitions and vowels. The intra-subject s.d. is the variation among the 5 repetitions, averaged (variance) over all subjects and all vowels. Mean values of fundamental frequencies are shown with between-subject and intra-subject standard deviation in Fig. 9.

Mean values. Fundamental frequency starting from about 300 Hz at 3 years, decreases slightly with age. However the largest decrease of fundamental frequency seems to occur between the ages of 3 and 6 years. Thirteen-year-old boys had an average fundamental frequency of 221.1 Hz, still 10% higher than that of adult males (201.2 Hz). Thirteen-year-old girls, on the other hand, had an average fundamental frequency of 239.8 Hz, not very different from that of adult females (220.9 Hz).

Between-subject standard deviation. Between-subject standard deviation was not dependent on age. It ranged from 20 to 43 Hz. Interestingly, 13-year-old boys showed a standard deviation of 66.4 Hz, which is higher than that found for all other age groups.

Intra-subject standard deviation and its relation to mean value. Thirteen-year-old children showed about a 40 Hz s.d., yielding a ratio of standard deviation to mean of 0.122. There was a gradual decreasing with age reaching a minimum value (12 Hz, 0.017) at age ten or twelve and after that age there was not further decrease in intra-subject standard deviation of fundamental frequency (0.01 to 0.0). This decrease in relative variability is shown in Fig. 10.

Adult F	220.9	10.3	10.1	0.15

Discussion

It is well known that the fundamental frequencies of children and adult females are higher than those of the adult male. The fundamental frequencies of the vowels of an adult female are about one octave higher than that of the adult male. Children have a fundamental frequency of about 300 Hz even up to the age of 8 and 10 years. There is no significant difference of fundamental frequency of speech between 7 and 8 years, or between boys and girls of those ages (Fairbanks, Herbert and Hammond 1949; Fairbanks, Wiley and Nassman 1949; Potter and Steinberg 1950; Peterson and Barney 1952).

It is also well known that regulation of fundamental frequency in voice is dependent on many factors, including the length of vocal cord and the regulation of movement of peripheral voice and speech musculature by central nervous system (Pressman, 1942; Hirikae 1943). In his anatomical study, Negus (1949) reported that the length of vocal cord is 3 mm at birth, 5.5 mm at 1 year, 7.5 mm at 5 years, 8 mm at age 6 1/2 years, 9.5 mm at 15 years, 12.5 to 17 mm in the adult female and 17 to 23 mm in the adult male. Vocal cords generally lengthen rapidly up to 6 years and gradually after 8 years.

A study of fundamental frequency and the size of larynx of boys from 12 to 15 years reported that rapid development of larynx, as related to change of voice, began at around 13 years and finished at approximately 15 years (Nalder 1965).

Fig. 9. Fundamental frequencies. The open circles are means averaged across repetitions, one for each subject in each age group. The vertical bars enclosed within horizontal brackets show the variation (s.d.) across repetitions, while those between rows head show the variation across subjects. The broken line joins means for girls only, but the solid line for boys.

The present study shows that fundamental frequency was about 300 Hz at age 3, then there is a remarkable decrease of about 30 Hz between 3 and 6 years, then a gradual decrease after 6 years to 220 Hz in 13-year-old boys. Thirteen-year-old girls have an average of 210 Hz, which is not significantly different from that of adult females (220 Hz).

There is a strong correspondence between the fundamental frequency reported here and the changes in the length of vocal cords reported by Negus (1949). Furthermore the fact that between-subject standard deviation

Fig. 10. Coefficient of variation of fundamental frequency over repetitions, expressed as ratio of s.d. to the frequency.

Discussion

It is well known that the fundamental frequencies of children are higher than those of the adult male. The fundamental frequencies of the vowels of an adult female are about one octave higher than of the adult male. Childen have a fundamental frequency of at least up to the age of 8 and 10 years. There is no significant difference in fundamental frequency of speech between 8 and 9 years, or between 10 and 11 years of those ages of children. Helbert and Hammond 1949, Farner and Johnson 1950, Poth and Schuler 1950, Peterson and Lehmann 1950.

It is also well known that regulation of fundamental frequency is related to many factors including the length of vocal cord, and the regulation of movement of peripheral vocal and speech musculature by central nervous system (Crossman 1952, Kiritoku 1951). In his anatomical study Nagata (1950) reported that the length of vocal cord is 3 mm at birth, 5.5 mm at 1 year, 7.5 mm at 5 years, 8 mm at age 8 1/2 years, 9.5 mm at 15 years, 12.5 to 17 mm in the adult female and 17 to 19 mm in the adult male. Vocal cords generally lengthen rapidly up to 8 years and gradually after 8 years.

A study of fundamental frequency and the size of larynx of boys from 12 to 15 years reported that rapid development of larynx as related to change of voice began at around 13 years and finished at approximately 15 years (Nalder 1965).

Fig. 9. Fundamental frequencies. The open circles represent mean values averaged across repetitions, within and between subjects for each age group. The vertical bars enclosed within horizontal lines show the variation (s.d.) across repetitions, while those between horizontal lines show the variation across subjects. The broken line joins means for girls and boys the age of 10 years.

The present study shows that fundamental frequency was about 300 Hz at age 3, then there is a remarkable decrease of about 30 Hz between 3 and 6 years, then a gradual decrease after 6 years to 220 Hz in 13-year-old boys. Thirteen-year-old girls have an average of 240 Hz, which is not significantly different from that of adult females (220 Hz).

There is a strong correspondence between the fundamental frequency reported here and the changes in the length of vocal cords reported by Yugo (1919). Furthermore the fact that between-subject standard deviation

Fig. 10. Coefficient of variation of age 3 fundamental frequency over repetitions, expressed as a percentage of mean frequency.

of thirteen year-old boys was higher than that of other age groups, showed that there are important changes and a rapid decrease of fundamental frequency after about 13 years in boys. This evidence agrees with the results reported by Naider (1965)

In summary fundamental frequency decreases markedly between the ages of 3 and 6 years, after which the decrease is gradual. At 13 years, girls have almost the same value of fundamental frequency as adult females, while that of boys still decreases after 13 years rapidly reaching the value of the adult male and corresponding to development of the larynx

V TEMPORAL FEATURES

Method

Wide band spectrograms were used for the measurement of one type of temporal feature in the words. We measured the interval between plosive releases and the subsequent voiced sounds. These time intervals were the gaps between [h] and the release from [l] in the word "blue" between [p] and [] in the word "pen" and between [l] and [ə] in the word "fall" respectively.

Results

Data for temporal features are summarized in Table 3 and Fig. 12.

Mean values. The time interval between [p] and [] in the word "pen" varied from 40 to 68 msec and between [l] and [ə] in the word "fall" from 60 to 84 msec. A statistically significant difference for the means was found between age groups and therefore we conclude that these time intervals, on the average, are independent of age.

Between-subject standard deviation. Between-subject standard deviation of time intervals between [h] and [l] in the word "blue" showed 7.9 to 21.2 msec (that of [p] and [] in the word "pen" 8.5 to 27.7 msec and that of [l] and [ə] in the word "fall" 10.4 to 22.5 msec). In this case too the variability among individuals for this time interval between phonemes is independent of age.

Intra-subject variability. Three-year-old children showed about 27 msec intra-subject standard deviation and then there was a rapid decrease in variability as a function of age. Variability reached a minimum value (8 to 10 msec) at age 7 or 8 years, this also corresponding to that of adults. Here, as for the formant frequencies, there is a systematic decrease of individual variability or an increase in the precision of timing, with age. This variability reaches its minimum adult value at a somewhat earlier age than for the vowel formant.

Discussion

There are several studies on voice-onset time and formant-transition time samples of temporal features of consonant (Lisker and Abramson, 1964, 1966; Liberman et al. 1957; Preston, Yeh-Hom-Hian and Stark, 1967; Ohman 1966). These studies, which have been done on the voice-onset time of adult speech, reported wide variability among subjects. Lisker and Abramson (1963) showed that the mean voice-onset time of [p] was 8 msec with a range of 20 to 120 msec. The mean for [t] was 70 msec with a range

of thirteen year-old boys was higher than that of other age groups, showed that there are important changes and a rapid decrease of fundamental frequency after about 13 years in boys. This evidence agrees with the results reported by Nalder (1965).

In summary fundamental frequency decreases markedly between the ages of 3 and 6 years, after which the decrease is gradual. At 13 years, girls have almost the same value of fundamental frequency as adult females, while that of boys still decreases after 13 years rapidly reaching the value of the adult male, and corresponding to development of the larynx.

V TEMPORAL FEATURES

Method

Wide-band spectrograms were used for the measurement of one type of temporal feature in the words. We measured the interval between plosive releases and the subsequent voiced sounds. These time intervals were the gaps between [b] and the release from [l] in the word "blue" between [p] and [] in the word "pen" and between [t] and [a] in the word "tall" respectively.

Results

Data for temporal features are summarized in Table 3 and Fig. 12.

Mean data: The time interval between [p] and [] in the word "pen" varied from 49 to 68 msec. and between [t] and [a] in the word "tall" from 60 to 84 msec. No statistically significant difference for the means was found between age groups and therefore we conclude that these time intervals, on the average, are independent of age.

Between-subject standard deviation: Between-subject standard deviation of time intervals between [b] and [l] in the word "blue" showed 7.9 to 21.2 msec. that of [p] and [] in the word "pen" 8.5-27.7 msec. and that of [t] and [a] in the word "tall" 10.4-22.5 msec. In this case too, the variability among individuals for this time interval between phonemes is independent of age.

Intra-subject variability: Three year-old children showed about 27 msec. of intra-subject standard deviation and then there was a rapid decrease in variability as a function of age. Variability reached a minimum value (9-10 msec.) at age 7 or 8 years, this value corresponding to that of adults. Here as for the formant frequencies, there is a systematic decrease of individual variability or an increase in the precision of timing, with age. The variability reaches its minimum or adult value at a somewhat earlier age than for the vowel formants.

Discussion

There are several studies on voice-onset time and formant-transition time as examples of temporal features of consonants (Lisker and Abramson, 1964-1965; Liberman *et al.* 1957; Preston, Yem Komshian and Stark, 1967; Ohman, 1968). These studies, which have been done on the voice-onset time of adult speech, reported wide variability among subjects. Lisker and Abramson (1965) showed that the mean voice-onset time of [p] was 58 msec. with a range of 20 to 120 msec. The mean for [t] was 70 msec, with a range

of thirteen year-old boys was higher than that of other age groups, showed that there are important changes and a rapid decrease of fundamental frequency after about 13 years in boys. This evidence agrees with the results reported by Nalder (1965)

In summary fundamental frequency decreases markedly between the ages of 3 and 6 years, after which the decrease is gradual. At 13 years, girls have almost the same value of fundamental frequency as adult females, while that of boys still decreases after 13 years rapidly reaching the value of the adult male and corresponding to development of the larynx.

Fig. 12 Intra subject s.d. for time intervals specified in the key (bottom of page)

same phonetic sequences. These two observations are in accord with those discussed above from other investigators with respect to voice-onset time. The new contribution is the systematic decrease in a subject's own variability as age increases. The apparent fact that this temporal feature of speech production reaches an adult-like minimum value at 7 or 8 years while a spectral feature like vowel-formant frequency continues to increase in individual precision to age about 12 years, suggests that the temporal aspect of speech defines phonemic categories earlier and more easily than does a frequency aspect. Perhaps this dichotomy strengthens the findings concerning discrimination at category boundaries, clearer for consonants (Liberman *et al.*, 1937) than for vowels (Stevens *et al.*, 1964).

Fig 11 Portions of spectrograms of the words "blue", "pen" and "tall" illustrating measurement of time interval between plosive and the voiced continuant that follow.

of 30 to 105 msec. Preston Yem Konishian and Stark (1987) reported that the distribution of the values of voice-onset time for children approximated the adult models.

The present study shows, with the results summarized above, the mean time intervals measured here do not change systematically with age and also that there is wide variation among individuals pronouncing the

		bought	9
		best	10
		book	11
		boot	12

In order to facilitate the identification of the vowel sample cards on which each vowel was numbered, listed and represented in a key word were distributed to each listener (Table 4). The listener was then to write the number of the identified vowel on an answer sheet. A retest practice was carried out on 80 items.

Results

A confusion matrix for each age group and listener group was made and the amount of information transmitted by each age group was calculated.

Six messages—six responses The results of forced-choice listening with six alternative choices are displayed in the confusion matrix of Table 5. The maximum number in any one cell is the product of 6 children times 5 repetitions times 10 listeners. Inspection of the column totals reveals that while all six stimuli were presented equally often, the six responses were not given equally often. Three columns deserve particular notice. The choice of [æ] and [] a distinct vowel was not a happy one for the dialect of St. Louis. Fig. 2 showed that the mean formant frequencies for these two vowel are not very far apart. Speakers in this region do not distinguish clearly the vowel in pen and has. Furthermore the listeners, including a greater variety of dialects, did not distinguish the two, giving as many as three times the response [] a [æ]. In addition the low response frequency for [a] probably comes about because in a non Eastern dialect this vowel never exists except as the first part of the diphthong [ai]. On the response card the [a] was exemplified by the word "bat" and the experimenter explained that the word was an example of the sound only in some Eastern dialects where the vowel of "bat, bath and Bob" are all different. Nonetheless, the vowel as illustrated on the card does not represent a much used phonemic category in the speech of most of our listeners.

The diagonal cells show the number of correct identifications out of 250. Expressed as percentages these measures of intelligibility of the six vowels are given in Table 6 and Fig. 13 for the several ages.

VI IDENTIFICATION OF VOWELS BY ADULT LISTENERS

Method

A long tape containing 1500 randomly distributed vowel samples was used for a listening task. These samples were taken from the original recordings and contained vowels produced by the subjects: five from age groups 3, 5, 7 and 9 years and ten from age groups 11, 13 and adult. Half of each of the three older groups was male and half female.

Small segments of tape were cut from the sentence recordings, which segments corresponded to steady, unchanging portions of the target vowel according to a listening criterion of the experimenter. Not all vowel samples remained steady for the same duration and thus the durations were in fact different, ranging from about 100 to 300 msec. According to Joos (1948) criterion for a minimum of 80 msec required for vowel identification, all of these samples should have been adequately long. A two-way classification analysis of variance of these durations for three widely separated ages showed that the sample durations, averaged over all vowels, were not significantly different for the different ages, but different vowels had different durations, that for [ɔ] being the longest in all cases. There was also a significant interaction between vowel and age.

Fortunately, for present purposes, the longest durations did not yield the highest intelligibility scores (*vide infra*). For example [ɪ] even though longest in all cases, was not as intelligible as several other vowels. We conclude therefore that in spite of variations in the duration of vowel samples used in the listening tests, such variations did not affect the intelligibility scores. The reason probably is that all durations were longer than the minimum necessary.

Each sample was followed by a 5 sec segment of blank tape before the next sample was joined. Also, during the listening sessions, each block of 80 items was followed by a 2 minute rest period.

Twenty normally hearing adults, 12 men and 8 women chosen from among the training students at Central Institute for the Deaf served as listeners. Ten of twenty listeners had to select an identification response from among six stimulus alternatives [i], [e], [æ], [a], [ɔ] and [u]. Another ten listeners made identifications among twelve alternatives [i], [ɪ], [e], [æ], [a], [ɑ], [ʌ], [ɔ], [o], [ʊ], [u].

Four loudspeakers were hung about 1.5 meters above the heads of listeners seated in two rows. The signal level at the listener's head was approximately 70 dB re 0.0002 dyne/cm² at the peak of the speech sound.

TABLE 4 Display-cards used by listeners with 6 or 12 alternative responses

i beet	1	i beet	1

In order to facilitate the identification of the vowel sample cards on which each vowel was numbered, listed and represented in a key word were distributed to each listener (Table 4). The listener was then to write the number of the identified vowel on an answer sheet. Pretest practice was carried out on 80 items.

Results

A confusion matrix for each age group and listener group was made, and the amount of information transmitted by each age group was calculated.

Six responses—six responses. The results of forced-choice listening with six alternative choices are displayed in the confusion matrix of Table 5. The maximum number in any one cell is the product of 5 children times 5 repetitions times 10 listeners. Inspection of the column totals reveals that, while all six stimuli were presented equally often, the six responses were not given equally often. Three columns deserve particular notice. The choice of [æ] and [] as distinct vowels was not a happy one for the dialect of St. Louis. Fig. 2 showed that the mean formant frequencies for these two vowels are not very far apart. Speakers in this region do not distinguish clearly the vowels in "pen" and "ban". Furthermore the listeners, including a greater variety of dialects, did not distinguish the two, giving as many as three times the response [æ] as []. In addition the low response frequency for [æ] probably comes about because in a non-Eastern dialect this vowel never exists except as the first part of the diphthong [ai]. On the response card the [] was exemplified by the word "bath" and the experimenter explained that the word was an example of the sound only in some Eastern dialects where the vowels of "bat, bath and Bob" are all different. Nonetheless, the vowel as illustrated on the card does not represent a much used phonemic category in the speech of most of our listeners.

The diagonal cells show the number of correct identifications out of 250. Expressed as percentages these measures of intelligibility of the six vowels are given in Table 6 and Fig. 13 for the several ages.

VI IDENTIFICATION OF VOWELS BY ADULT LISTENERS

Method

A long tape containing 1500 randomly distributed vowel samples was used for a listening task. These samples were taken from the original recordings and contained vowels produced by the subjects five from age groups 3, 5, 7 and 11 years and ten from age groups 11, 13 and adult. Half of each of the three older groups was male and half female.

Small segments of tape were cut from the sentence recordings, which segments corresponded to steady, unchanging portions of the target vowel according to a listening criterion of the experimenter. Not all vowel samples remained steady for the same duration and thus the durations were in fact different, ranging from about 100 to 300 msec. According to Ioss (1948) criterion for a minimum of 50 msec required for vowel identification, all of these samples should have been adequately long. A two-way classification analysis of variance of these durations for three widely separated ages showed that the sample durations, averaged over all vowels, were not significantly different for the different ages, but different vowels had different durations, that for [o] being the longest in all cases. There was also a significant interaction between vowel and age.

Fortunately for present purposes, the longest durations did not yield the highest intelligibility scores (*vide infra*). For example [i] even though longest in all cases, was not as intelligible as several other vowels. We conclude therefore that in spite of variations in the duration of vowel samples used in the listening tests, such variations did not affect the intelligibility scores. The reason probably is that all durations were longer than the minimum necessary.

Each sample was followed by a 5 sec segment of blank tape, before the next sample was joined. Also, during the listening sessions, each block of 80 items was followed by a 2 minute rest period.

Twenty normally hearing adults, 12 men and 8 women, chosen from among the training students at Central Institute for the Deaf served as listeners. Ten of twenty listeners had to select an identification response from among six stimulus alternatives [i] [e] [æ] [a], [ɔ], and [u]. Another ten listeners made identifications among twelve alternatives [i] [ɪ] [e] [ɛ] [æ] [a] [ɑ] [ʌ] [ɔ] [o] [ʊ] [u].

Four loudspeakers were hung about 1.5 meters above the heads of listeners seated in two rows. The signal level at the listeners' head was approximately 70 dB re 0.0002 dyne/cm² at the peak of the speech sound.

In order to facilitate the identification of the vowel sample cards on which each vowel was numbered, listed and represented in a key word were distributed to each listener (Table 4). The listener was then to write the number of the identified vowel on an answer sheet. Pretest practice was carried out on 80 items.

Results

A confusion matrix for each age group and listener group was made and the amount of information transmitted by each age group was calculated.

Six messages-six responses The results of forced-choice listening with six alternative choices are displayed in the confusion matrix of Table 5. The maximum number in any one cell is the product of 6 children times 6 repetitions times 10 listeners. Inspection of the column total reveals that, while all six stimuli were presented equally often, the six responses were not given equally often. Three columns deserve particular notice. The choice of [æ] and [ɪ] as distinct vowels was not a happy one for the dialect of St. Louis. Fig. 2 showed that the mean formant frequencies for these two vowels are not very far apart. Speakers in this region did not distinguish clearly the vowels in "pen" and "has". Furthermore, the listeners, including a greater variety of dialects, did not distinguish the two, giving as many as three times the response [ɪ] a [æ]. In addition the low response frequency for [a] probably comes about because in a non-Eastern dialect this vowel never exists except as the first part of the diphthong [aɪ]. On the response card the [a] was exemplified by the word "bath" and the experimenter explained that this word was an example of the sound only in some Eastern dialects where the vowel of "bat, bath and Bob" are all different. Nonetheless, the vowel illustrated on the card does not represent a much used phonemic category in the speech of most of our listeners.

The diagonal cells show the number of correct identifications out of 250. Expressed as percentages these measures of intelligibility of the six vowels are given in Table 6 and Fig. 12 for the several ages.

VI IDENTIFICATION OF VOWELS BY ADULT LISTENERS

Method

A long tape containing 1500 randomly distributed vowel samples was used for a listening task. These samples were taken from the original recordings and contained vowels produced by the subjects five from age groups 3-5-7 and 9 years and ten from age groups 11-13 and adult. Half of each of the three older groups was male and half female.

Small segments of tape were cut from the sentence recordings, which segments corresponded to steady unchanging portions of the target vowel according to a listening criterion of the experimenter. Not all vowel samples remained steady for the same duration and thus the durations were in fact different, ranging from about 100 to 300 msec. According to Joos (1948) criterion for a minimum of 50 msec required for vowel identification, all of these samples should have been adequately long. A two-way classification analysis of variance of these durations for three widely separated ages showed that the sample durations, averaged over all vowels, were not significantly different for the different ages, but different vowels had different durations, that for [a] being the longest in all cases. There was also a significant interaction between vowel and age.

Fortunately for present purposes, the longest durations did not yield the highest intelligibility scores (*vide infra*). For example [ɔ], even though longest in all cases, was not as intelligible as several other vowels. We conclude therefore that in spite of variations in the duration of vowel samples used in the listening tests, such variations did not affect the intelligibility scores. The reason probably is that all durations were longer than the minimum necessary.

Each sample was followed by a 5-sec segment of blank tape before the next sample was joined. Also, during the listening sessions, each block of 80 items was followed by a 2 minute rest period.

Twenty normally hearing adults, 12 men and 8 women, chosen from among the training students at Central Institute for the Deaf served as listeners. Ten of twenty listeners had to select an identification response from among six stimulus alternatives [i] [e] [æ] [a] [ɔ] and [u]. Another ten listeners made identifications among twelve alternatives [i], [ɪ] [e], [ɛ], [a], [ɑ], [ɔ], [ʌ], [o], [ɒ], [ɪ], [ʊ].

Four loudspeakers were hung about 1.5 meters above the heads of listeners seated in two rows. The signal level at the listener's head was approximately 10 dB re 0.0002 dyne/cm² at the peak of the speech sound.

It is clear that intelligibility of all vowels increases with the age of the talker and we assume that this effect is due to the change in variability that characterizes the consistency of repetition of such vowels, as discussed above in the measurement of formant frequencies.

From these values it is also clear that the several vowels are not equally intelligible [i] and [u] being the highest. On the other hand, these measures of relative intelligibility are contaminated by the response biases discussed above and illustrated by the column totals of Table 5.

Four types of analyses were made on the data of the confusion matrices, shown in Table II. These were, (a) conventional calculation of values of intelligibility indices for each vowel as spoken by each age group (Table 6) (b) determination of the amount of information transmitted within each confusion matrix, (c) estimation of the pairwise discriminability among

TABLE 6 *Intelligibility of six vowels spoken by subjects of different ages*

Uncorrected scores equal to number of correct responses divided by number of correct responses divided by number of vowels spoken for the six-alternative response. The last three rows give averaged results of both sexes in the groups 11 and 13 years, and adult

the vowels by use of the Constant Ratio Rule for vowels spoken by all but the two youngest groups, and (d) estimation of the probability of a correct identification of each of the vowels as spoken by each age group after applying a correction for response biases.

The intelligibility indices for each vowel were calculated by dividing the number of times that vowel was correctly identified by the number of presentations of that vowel. These are the measures shown in Table 6 and Fig. 13. They demonstrate a general improvement of performance on the identification task as a function of the age of the speakers, for all vowels with the exception of [æ] which apparently was something of a mystery to

Fig. 13 Intelligibility (percentage of times correctly identified) of the different vowels for each of the age groups.

TABLE 7 *Average information transmitted per vowel over all vowels spoken by talkers at different ages.*

Age	<i>H</i>	Age	<i>H</i>
3	1.020	11, F	1.600
5	1.169	12, M	1.571
7	1.582	12, F	1.574
9	1.693	Adult, M	1.641
11, M	1.213	Adult, F	1.645

the listeners. (The broken line in this figure is discussed in a later section.)

The amount of information transmitted within each confusion matrix yields a measure of identification performance averaged across the six vowels. This index may thus give a clearer picture of the general improvement in the discriminability of vowels as the speaker's age increases. Information transmitted (I) was calculated as suggested by Garner and Hake by finding the difference between response information (I) and response equivocation (E) where

$$I = - \sum_j p(n) \log_2 p(n)$$

and

$$E = - \sum_j p(A) \sum_n [p(n|A) \log_2 p(n|A)]$$

for a matrix of m rows (j) and columns (k) Information transmitted as a function of age of the speaker (shown in Table 7 Fig 14) reaches close to its maximum value by 7 years.

Consideration of the original confusion matrices demonstrates some problems not treated in the two preceding forms of analysis. As noted earlier the responses were not used equally often, and both information transmitted

Fig. 14 Information transmitted in vowel spoken by different age groups.

TABLE 7 Average information transmitted per vowel over all vowels spoken by talkers at different ages

Age	I	Age	I
3	1.020	11 F	1.699
5	1.169	12, M	1.571
7	1.562	12 F	1.374
9	1.892	Adult, M	1.611
11 M	1.215	Adult, F	1.615

the listeners. (The broken line in this figure is discussed in a later section.)

The amount of information transmitted within each confusion matrix yields a measure of identification performance averaged across the six vowels. This index may thus give a clearer picture of the general improvement in the discriminability of vowels as the speaker's age increases. Information transmitted (I) was calculated as suggested by Garner and Hake by finding the difference between response information (I) and response equivocation (E) where

$$I = - \sum_i p(a) \log_2 p(a)$$

and

$$E_i = - \sum_j p(A) \sum_a p(a | i) \log_2 p(a | i)$$

for a matrix of m rows (i) and columns (k). Information transmitted as a function of age of the speaker (shown in Table 7 Fig 14) reaches close to its maximum value by 7 years.

Consideration of the original confusion matrices demonstrates some problems not treated in the two preceding form of analysis. As noted earlier the responses were not used equally often, and both information transmitted

Fig 14 Information transmitted per vowel spoken by different age groups.

and intelligibility (simple per cent correct) may be degraded artificially by such response biases. That is, even though ability to identify each of the vowels be equal differences in response probability might yield the illusion of real variance in their identifiability. That this is not a trivial issue may be seen by examining the relative proportions of the responses [a] and [ɔ] in Table 5. Also it is fairly clear in the original matrices that these same two vowels are never very discriminable one from the other although they do appear to bear information in the sense that either one tends to lead to one of the two appropriate responses.

One method for handling these problems is through application of the "Constant Ratio Rule" proposed by Clarke (1957). Clarke's rule simply provides that the ratio between any two entries in a row of a submatrix is equal to the ratio between the corresponding two entries in the master matrix. In the present case this means that the pairwise discriminability of any two vowels can be estimated from the four entries associated with these vowels in the original six vowel matrix. For example the vowels [a] and [ɔ] were correctly identified 1060 and 1262 times, when pronounced by speakers from ages nine through adults. (In this analysis we have deleted data for the three younger groups, speakers from which were clearly less precise in their pronunciation than the older speakers.) The vowel [a] was identified as [ɔ] 191 times and [ɔ] as [a] 428 times. The constant ratio rule thus predicts that the results of an experiment on the discriminability of these two vowels would yield a matrix of conditional probabilities of the form

		Response	
		[a]	[ɔ]
Stimulus	[a]	817	153
	[ɔ]	253	747

It can be seen from this matrix that the response [a] is expected on fifty five per cent of the presentations of a vowel sound while [ɔ] is only expected to be used on forty five per cent (more serious imbalances may be found in the original confusion matrices). A now familiar index of discriminability which is relatively independent of such a response bias is the statistic introduced in signal detection theory d' . It is sufficient for this discussion to identify d' as the separation, in normal deviates, between a pair of overlapping equal variance normal distributions which could give rise to this discrimination matrix. (This statistic and its application to confusion matrices has been discussed in detail by Egan (1957).) Another way of expressing the discriminability between two such vowels is in terms of the maximum possible per cent of correct identifications ($P_{max}(C)$) if they were presented equally often. This measure is somewhat similar to an intelligibility index that has been corrected for guessing but it relies on well-demonstrated relations between response probability and the probability

TABLE 8 Discriminability (d') within all possible pairs of the 6 vowels spoken (a). Part (b) shows the maximum pairwise discrimination possible in terms of percent correct

						(50)

that the responses are correct (as opposed to older techniques which assumed that listeners make pure guesses. I.e. that when wrong they are responding totally independently of the immediate sensory stimulus). The value of $P_{\max}(C)$ is obtained by determining the particular criterion along a decision axis which maximizes the number of correct responses. In the case of equally probable stimuli it is the point where the probability that a given stimulus configuration is a sample from one distribution is the same as the probability that it is from the other. Table 8a gives the pairwise discriminability between the vowels, as estimated by the constant ratio rule in terms of the statistic d' for the vowels pronounced by talkers of age nine through adults. Table 8b presents the same information, but in terms of $P_{\max}(C)$. It can be seen from these tables that discriminability among most of the vowels was quite good, nearly perfect in many cases. However one of the combinations, [æ] versus [], actually produced negative values of d' . Also the discriminations of [a] from [æ] and of [] from [æ] are considerably poorer than the other twelve pairs which yielded positive values of d' .

In a further analysis we used a method similar to that described above to estimate the entries in the discrimination matrices, had they been made with ut response biases. Each of the six-by-six matrices was reduced to six different two-by-two matrices by the following technique. For each vowel (x) a matrix was constructed consisting of two rows, the stimulus vowels x and "not x " (\bar{x}) and of two columns, the identifications of x and \bar{x} where x represents all vowels other than x . Values of d' and of $P_{\max}(C)$ were

and intelligibility (simple per cent correct) may be degraded artificially by such response biases. That is, even though ability to identify each of the vowels be equal, differences in response probability might yield the illusion of real variance in their identifiability. That this is not a trivial issue may be seen by examining the relative proportions of the responses [a] and [ɔ] in Table 5. Also it is fairly clear in the original matrices that these same two vowels are never very discriminable one from the other although they do appear to bear information in the sense that either one tends to lead to one of the two appropriate responses.

One method for handling these problems is through application of the "Constant Ratio Rule" proposed by Clarke (1957). Clarke's rule simply provides that the ratio between any two entries in a row of a submatrix is equal to the ratio between the corresponding two entries in the master matrix. In the present case this means that the pairwise discriminability of any two vowels can be estimated from the four entries associated with these vowels in the original six vowel matrix. For example, the vowels [a] and [ɔ] were correctly identified 1060 and 1262 times, when pronounced by speakers from ages nine through adults. (In this analysis we have deleted data for the three younger groups, speakers from which were clearly less precise in their pronunciation than the older speakers.) The vowel [a] was identified as [ɔ] 191 times and [ɔ] as [a] 428 times. The constant ratio rule thus predicts that the results of an experiment on the discriminability of these two vowels would yield a matrix of conditional probabilities of the form

		Response	
		[a]	[ɔ]
Stimuli	[a]	817	153
	[ɔ]	253	747

It can be seen from this matrix that the response [a] is expected on fifty five per cent of the presentations of a vowel sound while [ɔ] is only expected to be used on forty five per cent (more serious imbalances may be found in the original confusion matrices). A now familiar index of discriminability which is relatively independent of such a response bias in the statistic introduced in signal detection theory d' . It is sufficient for this discussion to identify d' as the separation in normal deviates, between a pair of overlapping equal variance normal distributions which could give rise to this discrimination matrix. (This statistic and its application to confusion matrices has been discussed in detail by Egan (1957).) Another way of expressing the discriminability between two such vowels is in terms of the maximum possible per cent of correct identifications ($P_{max}(C)$) if they were presented equally often. This measure is somewhat similar to an intelligibility index that has been corrected for "guessing" but it relies on well-demonstrated relations between response probability and the probability

Fig. 18 Estimated percent correct and vowel intelligibility (uncorrected) averaged over the vowel ([æ] and [ɛ] combined) as a function of the age of the talker.

measures for this pair seem to show it to be more accurately identifiable than any single vowel is an example of the misleading effects of response bias.

The values of $P_{\max}(C)$ for the combined vowel [æ] or [ɛ], and for the five single vowels were averaged for each age group and are shown in Fig. 18, along with the corresponding averages of the intelligibility scores. These two curves demonstrate fairly clearly that the major improvement of identification performance as a function of the age of the speakers has been completed by age seven and also that the 'corrected' scores yield a considerably more stable function than the raw intelligibility measures. (The $P_{\max}(C)$ values here are related to the left hand ordinate and the intelligibility scores to the right for reasons indicated earlier.)

Six stimuli, twelve responses

In view of the variability among the speech-sound repetitions, particularly of the younger children, we wished to determine whether certain produced vowel sounded to adult like vowels not included in the original set of six. Half of the adult listeners were therefore given 12 alternatives from which to choose—a set that almost exhausts the repertory of American English. The results are shown in the confusion matrices of Table 9. The overall intelligibility (ratio of diagonal cells to 250) of the six intended vowels is shown in Table 10. The intelligibility of [ɪ] rises from 42% at age 3 to values round 80% while that for [u] starts at 53%. The other values are lower except for [ɛ] whose apparently high intelligibility is confounded by high response frequency for that vowel. The response frequencies for each group can be seen in the column totals in Table 9. Note that now many of the [ɪ] stimuli are called [i], probably because of short durations. Note also that many responses to a and ɔ are distributed under [a] and [ʌ] which does not

Fig. 15 Corrected estimate of intelligibility that takes into account chance performance and the unequal probabilities of response for the different vowels.

determined for each such matrix $P_{max}(C)$ here represents performance estimated under the assumption that x and \bar{x} are presented equally often, rather than with the ratio 1:5 as was actually the case. This assumption means only that 50% correct can be regarded as chance performance and it has no effect on the inter relation of the measures for the various vowels.) Fig. 15 shows the estimated values of $P_{max}(C)$ for each vowel as a function of age of the speakers. The trend discovered in the original intelligibility measures can be seen slightly more clearly here. It is reassuring to see that the major effects are not artifacts associated with response biases.

In the analysis using the constant ratio rule to determine the pairwise discriminability of the vowels for the older speakers, it was noted that the vowel $[e]$ was not discriminated from $[a]$ at better than a chance level. On further examination it was found that these two were likewise indiscriminable when spoken by the younger groups. Therefore the two vowels were treated as a single one to which either response was considered correct. Values of d' and $P_{max}(C)$ were estimated for each age of speaker from the matrices of the form

	or $ e $ or $ a $	
$ e $ or $ ae $		
$ e $ or $ ie $		

and the latter values are shown by the x 's which are connected by the dashed line in Fig. 15. It can be seen that identification of the pair $[e]$ or $[a]$ is quite accurate at all ages. A similar pairing of these two vowels was also made when calculating the initial intelligibility indices, and the results are shown by the dashed line and x 's of Fig. 13. That the intelligibility

available to 11 tenors under six alternatives. Finally and again probably reflecting the influence of short durations, many responses to [u] are now [ɔ]

The difficulties in any further analysis of a rectangular instead of a square matrix force us to provide this brief description only. In general the "high" vowels are sometimes identified as their neighboring [i] or [ɔ], and the middle vowels, already less intelligible under six alternatives, show a still more complicated pattern of response.

TABLE 9 *Confusion matrices (6 stimuli and 12 possible responses) for vowels spoken by talkers at different ages*

In this case the talkers had only 6 alternatives to produce while the listeners could choose from among 12 alternatives, the 12 containing the talker's 6 and 6 others.

their further report that if the entries were restricted to those that are identified correctly then the areas of overlap are considerably reduced. Furthermore if now one plots only vowels identified as correct by the talkers themselves, still less overlap is observed (Fairbanks and Grubb, 1961).

With the present results, we assume that a different kind of variability, namely variability within subjects that occurs over repetitions, yields less confusion or less overlap as the age of the talker increases. A similar notion is advanced by Okamura (1966) who demonstrated a striking reduction in these areas of overlap as the age of the children increased. What is different is that he showed this reduction and consequent improvement in vowel identification in two-dimensional plot of derivations of F_2 and F_3 given by $10 \log F_2 / (F_1 F_2 F_3)^{-2}$ and $10 \log F_3 / (F_1 F_2 F_3)^{-2}$ respectively.

TABLE 10 *Intelligibility of 6 vowels spoken by subjects at different ages when the listeners did not know which were 6 alternatives of the talkers, but only that they might have been any of 12*

Age (Yrs)	i	e	æ	u	o	Overall
3	42.4	42.0	18.0	6.0	31.0	32.3
5	42.8	60.6	5.6	8.0	15.2	33.3
	83.2	73.6	8.8	4.3	36.4	44.7
9	72.4	74.8	2.4	12.4	44.4	46.1
11 (♂)	48.3	70.8	1.6	8.4	50.5	47.7
11 (♀)	78.0	66.0	2.4	8.1	12.1	45.0
13 (♂)	68.4	80.0	2.4	8.7	43.1	47.6
13 (♀)	62.4	40.8	4.8	12.0	51.8	48.3
Ad lt (♂)	79.2	62.1	4.4	5.6	69.6	51.0
Adult (♀)	73.6	60.6	6.8	9.2	55.6	49.1

Discussion

The present results on vowel intelligibility agree in several respects with those of previous studies (Peterson and Barney 1952, Miller and Neely 1955 and Fairbanks and Grubb 1961). Previous intelligibility scores over all vowels are about 75% ranging from 53 to 92%. The vowels [i] and [u] appear always to be more intelligible than the middle vowels. The present results for adults show an average intelligibility of 72% with scores of 94 to 96% for [i] and [u] and 70% for [a]. The higher scores are associated with only six alternatives while previous studies have mostly used a vocabulary of from 10 to 12 vowels. The use of 12 alternative responses in the present study does not facilitate the comparison since those responses were to be associated with only six stimulus alternatives.

The main effect of course is that the identification of vowels increases with the age of the talker no matter whether vowel identification is measured by raw intelligibility scores, by amount of information transmitted or by an estimate of maximum percent correct that is free of listeners' response biases. Our interpretation is that particularly in these cases of listening where the listener has no opportunity to tune up to the speech of any talker the intelligibility of vowels depends in part on the consistency with which a given talker utters them. This consistency is the inverse of the intra-subject variability discussed above. The two effects are not completely parallel however since vowel formant variability continues to diminish as age increases to about 12 years, while the listening results reach maximum values for talker ages of only 7 years.

Variability among vowel formant frequencies is not a new phenomenon. Peterson and Barney (1952) displayed graphically the magnitude of variability among talkers by showing areas of overlap in a Formant 1-Formant 2 plot where exactly the same combination of frequencies represented two different intended vowels. Our results on vowel intelligibility agree with

their further report that if the entries were restricted to those that are identified correctly then the areas of overlap are considerably reduced. Further more if now one plots only vowels identified as correct by the talkers themselves, still less overlap is observed (Fairbanks and Grubb 1961)

With the present results, we assume that a different kind of variability namely variability within subjects that occurs over repetitions, yields less confusion or less overlap as the age of the talker increases. A similar notion is advanced by Okamura (1966) who demonstrated a striking reduction in these areas of overlap as the age of the children increased. What is different is that he showed this reduction and consequent improvement in vowel identification in two-dimensional plot of derivations of F_2 and F_3 , given by $10 \log P / (F_1 F_2 P)$ and $10 \log F_3 / (F_1 F_2 F)^{-2}$ respectively

VII GENERAL CONCLUSIONS AND DISCUSSION

The results from acoustical measurements of sentences spoken by 84 subjects show that the mean fundamental frequency and the mean first and second formant frequencies change systematically with the age of the talker roughly in accordance with predictions based on anatomical and physiological considerations. Changes in these means are most rapid in those early ages from 3 to 6 years when anatomical change has been noted as most rapid by others.

Of greater interest for present purposes was the change in precision or reproducibility of certain aspects of the speech sounds, namely the first and second formants of the vowels and one temporal aspect of the transition from a plosive consonant to the following vowel or semi vowel. Both formants show a clear decrease in variability on the successive repetitions of sentences for all vowels, though there are differences among the individual vowels in absolute values. The implication is clear that 3 year-old children do not move their tongues to exactly the same position for a particular vowel as it occurs in repetitions of the same sentence at least not so exactly the same as older children and adults. The variability decreases until about age 11.

Similarly the time interval between the explosion of a stop consonant and the following voiced sound is not exactly repeated time after time but rather shows a certain variability. This variability decreases from a maximum value at 3 years (the youngest age tested) to a minimum value at about age 8 somewhat earlier than was the case for minimum variability in the vowel formants.

The impetus for the present study came from observations of both authors on the intelligibility of speech of children in the countries where the authors' second languages were spoken, observations quite closely related to the concept of "phonemic category" as required in a motor theory of speech perception. Foreigners appear to have more difficulty understanding the speech of native children than do native speakers. If this difficulty is related to inaccuracy or sloppiness in the reproduction of the sounds of language, then it would appear that at least children's speech cannot be well described by relatively fixed sound categories. The present results on the decrease of this variability with age imply that a motor theory of speech perception must somehow be restricted to adults and older children where speech sounds can be regarded as relatively distinct habits.

Concepts of motor behavior controlled in part by sensory feedback are as old as the distinction between sensory and motor systems made around

1811 by Bell and Magendie. Early theories concerned voluntary movement and the idea was extended to nonvoluntary systems especially under the name of homeostasis.

Control of a motor system from sensory information arising in the motor system itself has been likened to the servo-system developed in several aspects of engineering theory (MacColl, 1945; Wiener 1948; Shannon and Weaver 1949; Davis, 1951; Peterson, 1953; Fairbanks, 1954; Brown and Campbell, 1948; Myaak, 1959; 1966).

The sensory information that is utilized for control of speech production arises in several sensory modalities. While there is much current interest in the forms of feedback from the musculature and articulating surfaces of the speech mechanism, we assume that the principal modality is auditory. We believe that our results illustrate the rather large error signals that arise in the early years of speech production, but also that the subsequent formation of rather fixed articulatory habits of position and of gesture involves smaller error signals and perhaps even less dependence on sensory feedback. That the feedback never goes to zero in normal talkers is shown by the deterioration of speech that follows the onset of moderate to severe losses of hearing.

In order for the auditory system to provide information about error to the speech-production system, the deviations in the speech output must, of course, be discriminated in hearing. With respect to the adult values for variability of formant frequencies, shown in Figs. 3-8, one might ask why does there remain an average global standard deviation of about 20 Hz for the first formant, and about 40 Hz for the second formant. Surely listeners can detect changes in the frequency of a pure tone that are smaller. On the other hand, changes in the peak region or formant of a complex tone are somewhat more difficult to discriminate as was shown by Flanagan (1955). Using the MIT POLO speech synthesizer he created artificial vowels in which one formant at a time could be varied in frequency. By presenting pairs of vowels in which either F_1 or F_2 was different, he obtained difference limens or just-noticeable differences of the order of 20 Hz for the first formant and about 40-80 Hz for the second formant, the latter depending more on the value of the comparison F_2 . In short the present variability measures in speech production are about as low as they could be if discriminable differences at the ear were the controlling or limiting factor.

It is not at all clear how perceptual discrimination develops. In the child's younger years, when his formant frequencies are so much more variable than those of the adult would his formant discrimination be similarly poor. Though formant discrimination has not been tested in young children, some recent observation on temporal features may provide a clue.

Variability in the time interval between the explosion in a plosive consonant and the voicing that follows, as illustrated in Fig. 12, reaches a minimum value (standard deviation) for the adult of approximately 10 msec. This rather precise performance in a language that contains only two

VII GENERAL CONCLUSIONS AND DISCUSSION

The results from acoustical measurements of sentences spoken by 84 subjects show that the mean fundamental frequency and the mean first and second formant frequencies change systematically with the age of the talker roughly in accordance with predictions based on anatomical and physiological considerations. Changes in these means are most rapid in those early ages from 3 to 6 years when anatomical change has been noted as most rapid by others.

Of greater interest for present purposes was the change in precision or reproducibility of certain aspects of the speech sounds, namely the first and second formants of the vowels and one temporal aspect of the transition from a plosive consonant to the following vowel or semi-vowel. Both for infants show a clear decrease in variability on the successive repetitions of sentences for all vowels, though there are differences among the individual vowels in absolute values. The implication is clear that 3 year-old children do not move their tongues to exactly the same position for a particular vowel as it occurs in repetitions of the same sentence at least not so exactly the same as older children and adults. The variability decreases until about age 11.

Similarly the time interval between the explosion of a stop consonant and the following voiced sound is not exactly repeated time after time but rather shows a certain variability. This variability decreases from a maximum value at 3 years (the youngest age tested) to a minimum value at about age 8 somewhat earlier than was the case for minimum variability in the vowel formants.

The impetus for the present study came from observations of both authors on the intelligibility of speech of children in the countries where the authors' second languages were spoken observations quite closely related to the concept of phonemic category as required in a motor theory of speech perception. Foreigners appear to have more difficulty understanding the speech of native children than do native speakers. If this difficulty is related to inaccuracy or sloppiness in the reproduction of the sounds of language then it would appear that at least children's speech cannot be well described by relatively fixed sound categories. The present results on the decrease of this variability with age imply that a motor theory of speech perception must somehow be restricted to adults and older children where speech sounds can be regarded as relatively distinct habits.

Concepts of motor behavior controlled in part by sensory feedback are as old as the distinction between sensory and motor systems made around

SUMMARY

Sound spectrograms were made of recordings of standard sentences spoken by each of 84 subjects—children ranging in age from 3 to 13 years, and adults. Sentences were repeated by each subject five times. Acoustical measures and statistical calculations concerned fundamental frequency and the first and second formant of vowels, and interphonemic temporal features of words. Adult listeners identified vowel segments taken from the recordings of several age groups.

Intra-subject variability that is, the acoustical repeatability of certain sounds in the sentences, for the vowel formant frequencies decreases as the age of the talker increases to 11 or 13 years. At least one interphonemic temporal feature also shows a decrease in variability with age but it reaches its minimum at an earlier age 7 or 8 years. Intelligibility of the vowels for adult listeners also increases with the age of the talker reaching maximum values for talkers of ages 8 or 9 years. Other results show changes in the mean fundamental frequency and the mean formant frequencies with age.

Relations between these results and anatomical-physiological development are discussed, as are also relations to language learning and phonemic categories.

SOMMAIRE

On a enregistré (magnetophone) des phrases parlées par chacun des 84 sujets, de l'âge 3 ans jusqu'à l'âge de 13 ans, et adultes. Chaque sujet a répété les phrases 5 fois. Les mesures acoustiques tirées des spectrogrammes, et les calculs statistiques ont concerné la fréquence fondamentale, les formants des voyelles, et certaines intervalles interphonémiques. De plus, des auditeurs adultes ont identifié les voyelles.

La variabilité intra-sujet pour les formants — c'est-à-dire l'inverse de la précision de la répétition des sons dans les phrases — décroît avec l'augmentation de l'âge du locuteur jusqu'à l'âge de 11 ou 13 ans, dès que la valeur est égale à la des adultes. La variabilité des intervalles temporels entre les consonnes plosives et les voyelles suivantes décroît aussi avec l'âge mais le minimum apparaît à l'âge de 7 ou 8 ans.

L'intelligibilité des voyelles pour les auditeurs adultes augmente avec l'âge des locuteurs, mais celle-ci atteint le maximum dès l'âge de 8 ou 9 ans. Des autres résultats concernant la changement avec l'âge des moyens des fréquences fondamentales et des fréquences formantes.

classes of plosive consonants, is necessary for some of the sharp distinctions involved in separating voiced from voiceless consonants. Such discrimination, however, appears already in the listening behavior of 7 year-old children according to Winterkorn *et al* (1967) who showed that such children accepted as "da" only those synthetic syllables with voice-onset time of 20 msec or less, and as "ta" those stimuli with 40 msec or more. But this is at an age when the present results show very great variability (Fig 12) with standard deviations as large as 26-28 msec.

While this line of evidence is neither abundant nor simple it appears that the variability under investigation in the present work is descriptive more of the motor control process than of perceptual capability at different ages.

Des rapports entre ces resultats et le développement anatomique et physiologique ainsi que le développement du langage et les catégories phonémiques, compriment la base de la discussion

ZUSAMMENFASSUNG

Sprachspektrogramme von Sätzen aufnahmen gesprochen von 84 Versuchspersonen im Alter von 3 bis 13 Jahren waren gemacht. Jede Versuchsperson wiederholte die Sätze fünfmal. Akustische Messungen und statistische Berechnungen der Grundfrequenz der Stimme, der ersten und zweiten Formantfrequenzen der Vokale und der interphonemischer Zellcharakteristiken waren durchgeführt. Vokalsegmente, die aus den originalen Aufnahmen von verschiedenen Altersgruppen genommen waren, waren mit erwachsenen Zuhörern identifiziert.

Die Intra-versuchspersonvariabilität, das heisst der Mangel der akustischen Wiederholungsfähigkeit einiger Laute in Sätzen, für die Formantfrequenzen der Vokale vermindert sich als das Alter zu 11 oder 13 Jahre steigt. Es vermindert sich mit dem Alter die Variabilität auch wenigstens einer interphonemischen Zellcharakteristike diese reicht aber Minimum im Alter von 7 bis 8 Jahren. Auch die Verständlichkeit der Vokale die mit erwachsenen Zuhörern geprüft war steigt mit dem Alter des Sprechers, und reicht maximale Werte bei 8 bis 9-jährigen Sprechern. Es waren dargestellt andere Ergebnisse die die Veränderung der mittleren Grundfrequenz der Stimme und der mittleren Formantfrequenzen zeigen.

Die Verhältnisse zwischen diesen Ergebnissen und der anatomisch physiologischen Entwicklung so wie auch das Verhältnis zum Lernen der Sprache und zu phonemischen Kategorien sind gezeigt.

INTRODUCTION

There are still pending a number of problems concerning functional disorders of the pharynx and esophagus noted on radiological examination. The etiology and pathogenesis of the majority of these phenomena are not clear and it cannot be determined whether some of them should be considered normal phenomena or pathological phenomena.

The purpose of this paper is to appraise clinical significance of these functional disorders by examining the relationships between them and organic lesions of the pharyngo esophageal region including the connected nervous system, and by investigating the incidence of these phenomena in normal persons of different age categories.

Under the term functional disorders of the pharynx and esophagus is included disorders of deglutition at the level of the pharynx, and dyskinesias and dystonias of the esophagus found radiologically. In the present study following eleven phenomena are discussed i. e. hesitant deglutition, pharyngeal stasis, piecemeal deglutition, pharyngeal laxity asymmetrical deglutition, regurgitation into the epipharynx, aspiration into the trachea, pharyngo esophageal spasm, regurgitation into the pharynx, tertiary contractions and functional diverticula.

RESULTS AND COMMENT

Hesitant Deglutition

Hesitant deglutition consists of difficulty in moving the barium bolus from the oral cavity to the pharynx. The barium bolus is stagnant on the back of the tongue, and many swallowing movements must be repeated before the bolus is projected into the pharynx. Sutherland (1962) described that this particular form of dysphagia takes two or more swallows to force the food out of the mouth or in severer cases no matter how much the food is chewed it goes "round and round" but won't go down.

In the present study hesitant deglutition was observed in only three cases aged more than 60 years in the normal group as shown in Table 1. Its degree in these normal cases was slight, and no dysphagia for ordinary foods was complained of. Considering the fact that the phenomenon is observed in the normal group in only aged persons, it is presumed that the phenomenon may be ascribed to a tendency to xerosis in the oral cavity resulting from senile atrophy of the mucous membrane and to latent hypokinesia in swallowing.

In the clinical group as shown in Table 2, this sign was observed in 23 cases. It occurred most frequently in cases with pharyngeal paralysis, suggesting that it is one of the most important radiological signs of paralytic disease of the pharynx. This sign was observed in six cases with malignant tumors, and is considered to be due to the decreased swallowing function accompanied by general debility (Fig. 1-2). Furthermore, hesitant deglutition was found in one case of ulcerous

TABLE 1 *Incidence of the functional disorders of the pharynx and esophagus in normal subjects*

Age	Number	Hesitant deglutition	Pharyngeal stasis	Asymmetrical deglutition	Tertiary contractions
21-30	30	0	2	2	2
31-40	20	0	3	1	4
41-50	20	0		3	8
51-60	20	0	7	2	10
Over 61	20	3	16	2	13
Total	100	3	30	10	35

METHOD

Subjects are divided into a normal group and a clinical group. The normal group comprises 100 healthy persons who have no subjective symptoms and show no pathological findings on otolaryngologic examination. There are five subgroups of 20 persons each, aged 21 to 30 years, 31 to 40 years, 41 to 50 years, 51 to 60 years and more than 60 years. The clinical group consists of 258 patients who have any subjective symptoms in the pharynx or esophagus and who have been proven to have any organic disease which causes their subjective symptoms.

Fluoroscopic examination was carried out in all cases, and fluoroscopic views considered to be useful were supplemented by fixed X ray films. When required cine fluorography was accomplished and the findings were examined subsequently. All of the subjects were examined in standing position and supine position each by anterior, lateral, right anterior oblique and left anterior oblique projections. The radioopaque medium used in this study was Bargin S₁® which contains 78.1 g of barium sulfate per 100 ml. The dose for a single swallow was kept almost constant.

RESULTS AND COMMENT

Hesitant Deglutition

Hesitant deglutition consists of difficulty in moving the barium bolus from the oral cavity to the pharynx. The barium bolus is stagnant on the back of the tongue, and many swallowing movements must be repeated before the bolus is projected into the pharynx. Sutherland (1962) described that this particular form of dysphagia takes two or more swallows to force the food out of the mouth or in severer cases, no matter how much the food is chewed it goes "round and round" but won't go down.

In the present study hesitant deglutition was observed in only three cases aged more than 60 years in the normal group as shown in Table 1. Its degree in these normal cases was slight, and no dysphagia for ordinary foods was complained of. Considering the fact that the phenomenon is observed in the normal group in only aged persons, it is presumed that the phenomenon may be ascribed to a tendency to xerosis in the oral cavity resulting from senile atrophy of the mucous membrane and to latent hypokinesia in swallowing.

In the clinical group, as shown in Table 2, this sign was observed in 23 cases. It occurred most frequently in cases with pharyngeal paralysis, suggesting that it is one of the most important radiological signs of paralytic disease of the pharynx. This sign was observed in six cases with malignant tumors, and is considered to be due to the decreased swallowing function accompanied by general debility (Fig. 1-2). Furthermore hesitant deglutition was found in one case of ulcerous

METHOD

Subjects are divided into a normal group and a clinical group. The normal group comprises 100 healthy persons who have no subjective symptoms and show no pathological findings on otolaryngologic examination. There are five subgroups of 20 persons each, aged 21 to 30 years, 31 to 40 years, 41 to 50 years, 51 to 60 years and more than 60 years. The clinical group consists of 258 patients who have any subjective symptoms in the pharynx or esophagus, and who have been proven to have any organic disease which causes their subjective symptoms.

Fluoroscopic examination was carried out in all cases, and fluoroscopic views considered to be useful were supplemented by fixed X-ray films. When required cine fluorography was accomplished and the findings were examined subsequently. All of the subjects were examined in standing position and supine position each by anterior, lateral, right anterior oblique and left anterior oblique projections. The radioopaque medium used in this study was Bargin S₁[®] which contains 78.1 g of barium sulfate per 100 ml. The dose for a single swallow was kept almost constant.

esophagitis in one case of dermatomyositis and in one case of Plummer Vinson syndrome. Of these the case of Plummer Vinson syndrome was accompanied by pharyngeal spasm and severe xerostomia with smooth tongue.

Pharyngeal Stasis

Pharyngeal stasis is characterized by stagnation of the barium residues in the vallecula and the piriform fossae or either of them in spite of several complementary swallowing movements following the first. This sign was first reported as "dysphagia atonica" by Holzknecht and Olbert (1910), and subsequently has been noted by many investi-

years of age. As was mentioned by Lindsay (1955), in advanced senility there may be atrophy and hypokinesia of the pharyngeal muscles and less smooth co ordination of the swallowing movements which causes stagnation of food or barium in the vallecula and piriform sinuses.

In the clinical group pharyngeal stasis was observed in 83 cases out of 158 or 52 per cent indicating that this phenomenon is the

Fig. 2. Anteroposterior view. Barium stasis in the oral cavity and aspiration into the trachea, in a woman aged 62 years, suffering from postcricoid cancer.

most common sign of the kinetic disorders of the pharynx (Table 2). Almost all cases of neurological disease with pharyngo-esophageal symptoms, such as progressive bulbar paralysis, pseudobulbar paralysis, Parkinson's disease, pharyngeal paralysis and amyotrophic lateral sclerosis showed this sign (Fig 4-5). It was noted that in these neurological diseases the stasis was accompanied frequently by other dyskinetic phenomena such as hesitant deglutition, piecemeal deglutition, pharyngeal laxity etc. It is also interesting to note that stasis was observed in 4 cases of 8 suffering from recurrent laryngeal nerve paralysis.

Furthermore this phenomenon was observed in various organic lesions of the hypopharynx and upper esophagus such as malignant tumors, hypopharyngeal diverticula, cervical esophagitis, periesophageal abscess, cervical spondylitis etc. (Fig 1-6, -8-9-10). It is presumed that these organic lesions, except for diverticula, increase the resistance at the affected areas against the passage of barium bolus, which induces its stagnation. The fact that this condition occurs almost exclusively

also observed in several cases of malignant tumors of the cervical esophagus and other regions.

Pharyngeal Laxity

Pharyngeal laxity is represented by dilatation of the pharynx on radiographic studies. The pharyngeal cavity dilates laterally and forward remarkably and gives a patulous, atonic, sac like appearance in the anteroposterior view. When the Valsalva manoeuvre is carried out, this phenomenon is much more apparent than in the resting phase. Thus, the examination for this phenomenon ought to be carried out in the resting phase and at the time of the Valsalva manoeuvre.

In our study the condition was observed in 5 cases of pharyngeal paralysis, in one case of Parkinson's disease and in one case of amyotrophic lateral sclerosis, all of them being associated with pharyngeal stasis (Table 2 and Fig. 4).

Pharyngeal laxity is due to a decrease in pharyngeal tonus and its existence can be reliable evidence of neurogenic disorders of the swallowing mechanism.

Fig. 3. Anteroposterior view. Barium stasis in the valleculae and right piriformis sinus, in a woman aged 45 years. Note the phenomenon of asymmetrical deglutition, which in this case appears to have no pathological significance.

in lesions of the pharynx and upper esophagus and seldom in those of the middle and lower esophagus may support this assumption. For the cases with hypopharyngeal diverticula the stasis is considered to result from decreased intrapharyngeal pressure during swallowing.

Piecemeal Deglutition

Piecemeal deglutition represents the phenomenon in which barium bolus is not pushed into the esophagus as a whole by a single swallowing but is moved in separate small quantities by several successive swallowing movements.

This phenomenon was not observed in the normal group. In the clinical group it was observed in patients with pharyngeal paralysis, pseudobulbar paralysis, Parkinson's disease, amyotrophic lateral sclerosis and recurrent laryngeal nerve paralysis, mostly accompanying hesitant deglutition, pharyngeal stasis or pharyngeal laxity (Table 2). It was

Fig. 6. Asymmetrical deglutition, in man aged 66 years, suffering from cancer of the cervical esophagus. Left Anteroposterior view during the active phase. Right Right lateral view during the resting phase. Barium stagnates markedly in the valleculae and piriform sinuses.

it is essential to ensure that the patient is placed in the true antero-posterior position in order to derive from this sign its true diagnostic value.

In the clinical group as presented in Table 2, this sign was observed in 8 cases of neurogenic lesions, 10 cases of malignant tumors localized to the pharyngo-esophageal region, 4 cases of esophageal diverticula, 3 cases of cervical spondylosis, 2 cases of Plummer-Vinson syndrome and in some other cases (Fig. 5 & 9-11-12). Since this condition is observed not rarely in normal subjects, it is difficult to confirm that the condition is a pathognomonic sign of any disease. However, when this sign is found along with other functional disorders such as hesitant deglutition, piecemeal deglutition, tracheal aspiration and if neurogenic disorders can be excluded, development of a malignant tumor involving the pharynx, larynx and cervical esophagus is strongly suspected.

Regurgitation into the Epipharynx

Regurgitation of barium into the epipharynx is one of the most

Fig. 5. Anteroposterior view Barium stasis in the piriform sinuses and asymmetrical deglutition in a man aged 55 years, suffering from pseudobulbar paralysis.

Asymmetrical Deglutition

In normal persons a barium bolus is ordinarily observed to pass symmetrically from the piriform sinus on both sides to the esophagus in the anteroposterior projection of the fluoroscopic examination. Asymmetrical deglutition is characterized by an asymmetrical or one sided passage of the bolus through the piriform sinuses.

In the present study this sign was found about 10 per cent of the time in every age category of the normal group (Table 1). No age predominance was noted in the incidence of this phenomenon. In these normal subjects the asymmetrical sign disappeared when they extended the neck of the obstructed side. On the contrary when a normal person without asymmetrical deglutition turn his head to one side at the time of swallowing the passage of the barium bolus through the piriform sinus of that side is hindered. These facts show that the occurrence of the phenomenon is closely related with asymmetry of the tonus of the neck muscles. Therefore as was noted by Brombart

Fig. 8. Asymmetrical deglutition. III man aged 60 years suffering from cancer of the cervical esophagus. Left Anteroposterior view during the active phase. Right Right lateral view during the resting phase. Barium stagnates markedly in the valleculae and piriform sinuses.

It is essential to ensure that the patient is placed in the true antero-posterior position in order to derive from this sign its true diagnostic value.

In the clinical group as presented in Table 2, this sign was observed in 8 cases of neurogenic lesions, 10 cases of malignant tumors localized to the pharyngo-esophageal region, 4 cases of esophageal diverticula, 3 cases of cervical spondylitis, 2 cases of Plummer-Vinson syndrome and in some other cases (Fig. 5, 6, 9, 11, 12). Since this condition is observed not rarely in normal subjects, it is difficult to confirm that the condition is a pathognomic sign of any disease. However, when this sign is found along with other functional disorders such as hesitant deglutition, piecemeal deglutition, tracheal aspiration, and if neurogenic disorders can be excluded, development of a malignant tumor involving the pharynx, larynx and cervical esophagus is strongly suspected.

Regurgitation into the Epipharynx

Regurgitation of barium into the epipharynx is one of the most

Fig. 7 Anteroposterior view. Barium stasis in the maxillary and piriform sinuses, in a man aged 49 years suffering from posteroal cancer.

common signs in patients with vocal insufficiency, and is observed readily on lateral projection. In the present study, however, this sign was observed in only 2 cases, one case of Parkinson's disease and one case of pharyngeal paralysis (Fig. 14).

Aspiration into the Trachea

Aspiration of barium into the trachea was first observed fluoroscopically by Landau (1923). This phenomenon is induced by insufficient closure of the laryngeal aperture resulting from neurogenic obstacles or organic diseases. Bachman (1959) classified the causes of this phenomenon as follows:

- A. Abnormalities of neurogenic origin
 - 1 Faulty timing of the stages with respect to passage of the bolus.
 - 2 Inability of the various furrows to close completely and form an effective seal against the leakage of fluid past them.
 - 3 Inability of the various furrows to remain closed for the entire period during which the swallowed fluid is passing by.
- B. Organic diseases in the laryngopharynx

Fig. 8. Anteroposterior view during Valsalva maneuver. Barium stasis in the valleculae and lateral hypopharyngeal diverticulosis, in a man aged 51 years, complaining of slight dysphagia.

1. Mechanical obstruction of a mass.
2. Limited mobility of arytenoids or epiglottic folds due to neoplastic or inflammatory infiltration.
3. Surgical procedures on the laryngopharynx.

In our series this phenomenon was not observed in the normal group. It was observed in 8 cases of neurogenic lesions and 12 cases of neoplastic tumors (Fig. 11). In addition one case of cervical esophagitis and one case of dermatomyositis showed this sign. It should be noted that this sign was always accompanied by pharyngeal stasis.

Pharyngo Esophageal Spasm

Spasm of the pharyngo esophageal sphincter is observed fluoroscopically as a depression or indentation of the posterior wall of the hypopharynx at the level of the body of the sixth or seventh cervical vertebra. This finding is observed not rarely during radioscopic examination in patients without any pharyngeal complaint, and it is difficult

Fig. 9. Anteroposterior view. Asymmetrical deglutition, in a man aged 50 years suffering from cervical spondylitis.

to attribute to it any pathological significance. Brunner (1952) postulated that a transitory hypopharyngeal bar is due to spastic contraction of the cricopharyngeous muscle while the spontaneous, or permanent hypopharyngeal bar is caused by permanent contracture of the cricopharyngeal muscle.

In our experience this condition was recognized in 3 cases of Plummer Vinson syndrome one of them being accompanied by mesopharyngeal spasm (Fig. 13).

Considerable difference of opinion is expressed in regard to the main pathologic findings accepted as the cause of dysphagia in the Plummer Vinson syndrome. Müller and Csipö (1962) claimed that dysphagia in the Plummer Vinson syndrome is due to dryness of the pharyngo esophageal mucous membrane and spasm of the cricopharyngeal muscle. On the contrary Brombart stressed diffuse esophagitis with chronic inflammatory infiltration and the formation of semilunar membranes or webs inserted on the anterior wall of the hypopharynx immediately below the cricoid cartilage. McNab Johns (1961) described

Fig. 10. Anteroposterior view. Barium stasis in the valleculae in man aged 73 years, suffering from cervical spondylosis.

that there were 19 cases with an abnormal barium swallow out of 39 cases radiologically examined. It was possible to get a satisfactory follow up in 17 of these 19 cases. He observed typical web formation in the hypopharynx in 12 of 17 cases. In the remaining 5 cases there was well marked persistent spasm and narrowing of the hypopharynx, but no web formation.

Regurgitation into the Pharynx

The barium bolus, after moving into the esophagus once, flows back into the pharynx again. This sign was observed in our series only in 2 cases of cancer of the thoracic esophagus. The appearance of this sign in these cases is attributed to the stenosis of the esophagus at the level of the lesions and the decrease in tonus of the pharyngo-esophageal sphincter.

Tertiary Contractions

In early papers (Cannon 1907, Carlson and Luckhardt 1914

Fig 9 Anteroposterior view Asymmetrical deglutition in a man aged 50 years suffering from cervical spondylosis.

to attribute to it any pathological significance Brunner (1952) postulated that a transitory hypopharyngeal bar is due to spastic contraction of the cricopharyngeus muscle while the spontaneous or permanent hypopharyngeal bar is caused by permanent contracture of the cricopharyngeal muscle.

In our experience this condition was recognized in 3 cases of Plummer Vinson syndrome one of them being accompanied by mesopharyngeal spasm (Fig 13).

Considerable difference of opinion is expressed in regard to the main pathologic findings accepted as the cause of dysphagia in the Plummer Vinson syndrome. Müller and Csipő (1962) claimed that dysphagia in the Plummer Vinson syndrome is due to dryness of the pharyngo esophageal mucous membrane and spasm of the cricopharyngeal muscle. On the contrary Brombart stressed diffuse esophagitis with chronic inflammatory infiltration and the formation of semilunar membranes or webs inserted on the anterior wall of the hypopharynx immediately below the cricoid cartilage. McNab Johnes (1961) described

Fig. 12. Anteroposterior view in cinefluorography. Asymmetrical deglutition in a man aged 61 years, suffering from cancer of the cervical esophagus. Left and center. Asymmetrical deglutition during the active phase of deglutition. Right. Barium stasis in the valleculae after cessation of deglutition.

Curling is usually asymptomatic but may produce esophageal pain. Templeton (1948) did not consider this type of contraction to be entirely normal, as they are not seen often in younger age groups, but are encountered frequently in older individuals.

In accordance with Templeton's observation the results obtained from our series of normal subjects shows that the sign was rare in the age groups younger than 40 years, but was more and more frequently encountered among older individuals (Table 1).

In the clinical group this sign was observed in various lesions. Table 2 shows that cervical esophagitis and cervical spondylosis are the lesions which cause this condition most frequently (Fig. 15, 16-17).

Tertiary contractions are observed almost exclusively at the level below the aortic arch of the esophagus and quite exceptionally at any higher level. Cinefluoroscopic examination revealed that the duration of the contractions ranged from 1.1 seconds to 11.9 seconds, most of

Fig. 11 Anteroposterior view Asymmetrical deglutition and aspiration into the trachea, in a man aged 61 years suffering from hypopharyngeal cancer

Jurica 1928) this phenomenon was reported as tortly peristalsis or localized contractions. Thereafter various names such as curling rippling Kräuselung intermittent spasms transitory autonomic contractions and tertiary contractions have been given to this phenomenon Its fluoroscopic appearance is characterized by simultaneous irregular contractions of the distended esophagus in the portion below the level of the aortic arch. At the height of the contraction the lumen assumes a peculiar irregular serrated appearance The contractions may be only fleeting or may last for several seconds. They are usually accompanied by a tonic phase which diffusely narrows the lumen (Templeton 1948). Brombart described that there is a surge of irregular very close contractions generally invading the lower two thirds or three quarters of the esophagus, following each other with such rapidity that they appear to occur simultaneously

Shelnmel et al. (1949) described this sign as follows (1) Curling is uncommon but not rare (2) Curling is believed to be produced by incoordinated unrelated segmental spasms of the smooth muscle. (3)

Fig. 12. Anteroposterior view in cinefluorography. Asymmetrical deglutition in man aged 61 years, suffering from cancer of the cervical esophagus. Left and center. Asymmetrical deglutition during the active phase of deglutition. Right. Barium stands in the valleculae after cessation of deglutition.

Curling is usually asymptomatic but may produce esophageal pain. Templeton (1948) did not consider this type of contraction to be entirely normal, as they are not seen often in younger age groups, but are encountered frequently in older individuals.

In accordance with Templeton's observation the results obtained from our series of normal subjects shows that the sign was rare in the age groups younger than 40 years, but was more and more frequently encountered among older individuals (Table 1).

In the clinical group this sign was observed in various lesions. Table 2 shows that cervical esophagitis and cervical spondylosis are the lesions which cause this condition most frequently (Fig 15 18, 17).

Tertiary contractions are observed almost exclusively at the level below the aortic arch of the esophagus and quite exceptionally at any higher level. Cinefluoroscopic examination revealed that the duration of the contractions ranged from 1.1 seconds to 11.9 seconds, most of

Fig. 13. Anteroposterior view in cinefluorography during the active phase of deglutition. Spasms are observed simultaneously at the level of the mesopharynx and pharyngo-esophageal junction in a woman aged 41 years suffering from Plummer Vinson syndrome.

them being between 2 and 5 seconds (Fig. 18).

As to the time relationship between the occurrence of this phenomenon and primary peristalsis of the esophagus the following three types were observed: (1) occurrence at the semi evacuation stage of the esophagus after the passage of primary peristalsis, (2) occurrence just after the passage of primary peristalsis, (3) occurrence simultaneously with primary peristalsis. Of these the first type was most frequently encountered.

The mechanism of this type of contractions has not been made clear. Since the phenomenon is peculiar to the smooth muscle portion of the esophagus and is observed more frequently in older individuals, it is presumed that the phenomenon is a sign of a neuromuscular incoordination of the esophagus.

Functional Diverticula (Tired Spasms)

The present phenomenon was first reported by Bárány in 1926 as functional diverticula and thereafter various terms such as false diverticula, tired spasms, pearl necklace esophagus and corkscrew esophagus

Fig. 14. Right lateral view in cinefluorography. Regurgitation into the epipharynx, in man aged 51 years, suffering from paralysis of the pharynx.

Fig. 15. Right anterior oblique view. Tertiary contractions in the lower two-thirds of the thoracic esophagus in the same case as in Fig. 10.

were also used for this phenomenon

Several symmetrical and circular contractions occur simultaneously in a part of the esophagus accompanied by round diverticulum like swellings between the strictures, taking on the appearance of a neck lace of large beads. It appears suddenly, lasts several seconds and disappears suddenly again. After its disappearance the esophagus resumes a smooth and straight outline. Similarly to tertiary contractions, this condition occurs almost exclusively in the subaortic part of the esophagus. It is noted that when the phenomenon occurs repeatedly in a patient each diverticulum like swelling is apt to appear almost at the same place in the esophagus.

In the present study functional diverticula were not found in any normal subjects. They were observed in 6 patients, representing

Fig 18. Duration of tertiary contractions measured by means of cinefluorography in 7 patients.

one case each with laryngeal cancer thyroid cancer hypopharyngeal diverticula cervical esophagitis, esophageal diverticula and Plummer Vinson syndrome respectively. The patients ranged in age from 43 to 67 years, and complained of dysphagia in 3 cases, discomfort in the sternal region in one case feeling of esophageal stenosis in one case and pharyngeal pain in one case partly being due to the accompanying pharyngo esophageal lesions (Fig 19 20 21 22). Brombart reported that this phenomenon is nearly always accompanied by dysphagia and as soon as the spasms occur the patient is painfully aware of them.

The genesis of functional diverticula still remains obscure, as is the case with tertiary contractions. Bárony and Polgár (1927) noted that this phenomenon can occur reflexly from affections of the stomach and duodenum. Brombart confirmed the fact and stated that the very frequent association of esophageal dyskinesias with ulcers of the duodenum forms a very valuable argument in favour of the hypothesis

Fig. 19. Right anterior oblique view. Functional diverticula in the lower third of the esophagus, in man aged 61 years, complaining of substernal distress.

that tertiary contractions and functional diverticula are due to a nervous condition or to a neuromuscular incoordination dependent on some reflex. Ungerecht (1963) also indicated frequent occurrence of this phenomenon in patients with true esophageal diverticulum, hiatus hernia, esophagitis, gastric ulcer duodenal ulcer cholecystitis, and diseases of the heart and the vessels.

Tertiary contractions and functional diverticula bear similarities in their preferred age and site of occurrence. However a definite difference between them exists with regard to incidence. Functional diverticula are not found in normal persons, whereas tertiary contractions are rather common phenomena, at least in old individuals.

Fig. 20. Functional diverticula and permanent diverticulum in a woman aged 43 years complaining of slight dysphagia. Classification of the Functional Disorders of the Pharynx and the Esophagus

On the basis of results obtained from our study the above mentioned eleven functional disorders are classified into the following four categories from the standpoint of their incidences.

1. Those observed in normal adults, especially in older age groups: pharyngeal stasis, tertiary contractions.
2. Those observed in normal adults uniformly at all ages: asymmetrical deglutition.
3. Those observed rarely in normal persons: hesitant deglutition.
4. Those never observed in normal persons: piecemeal deglutition, pharyngeal laxity, regurgitation into the epipharynx, aspiration into the trachea, pharyngo-esophageal spasm, regurgitation into the pharynx, functional diverticula.

Fig. 20. Functional diverticula and permanent diverticulum in a woman aged 43 years, complaining of slight dysphagia. Left Right anterior oblique view functional diverticula during the extreme stage of contraction. Right Anteroposterior view during resting phase the bulge persists after cessation of functional diverticula as permanent diverticulum.

SUMMARY

For the purpose of evaluating clinical significance of functional disorders of the pharynx and esophagus, the authors investigated roscopic findings of 100 normal healthy persons, and 258 patients with pharyngo-esophageal lesions.

The results obtained lead to the following conclusions:

1. Hesitant deglutition, pharyngeal stasis, piecemeal deglutition, pharyngeal laxity and aspiration into the trachea are important findings of central or peripheral paralysis of deglutitory function. In the majority of cases, two or more phenomena are observed simultaneously in the same patient.

2. Pharyngeal stasis is observed in normal subjects, especially in older age groups. In these normal cases, the phenomenon is considered a sign of subclinical hypokinesia of swallowing.

3. Pharyngeal stasis and asymmetrical deglutition are often important indirect radiologic findings in malignant tumors of the hypopharynx or cervical esophagus.

4. When asymmetrical deglutition is observed, an imbalance of the tonus of the left and right neck muscles should be kept in mind.

5. Tertiary contractions are observed frequently in normal individuals of higher ages.

6. Functional diverticula are rather rare phenomena, observed exclusively in patients with organic lesions of the pharynx, esophagus or other parts of the digestive tract.

Fig. 22. Right anterior oblique view. Functional diverticula of the esophagus in a woman aged 77 years, complaining of slight dysphagia after laryngectomy

SUMMARY

For the purpose of evaluating clinical significance of functional disorders of the pharynx and esophagus, the authors investigated fluoroscopic findings of 100 normal, healthy persons, and 253 patients with pharyngo-esophageal lesions.

The results obtained lead to the following conclusions:

1. Hesitant deglutition, pharyngeal stasis, piecemeal deglutition, pharyngeal laxity and aspiration into the trachea are important findings in central or peripheral paralysis of deglutitory function. In the majority of cases, two or more phenomena are observed simultaneously in a same patient.

2. Pharyngeal stasis is observed in normal subjects especially in older age groups. In these normal cases, the phenomenon is considered a sign of subclinical hypokinesia of swallowing.

3. Pharyngeal stasis and asymmetrical deglutition are often important indirect radiologic findings in malignant tumors of the hypopharynx or cervical esophagus.

4. When asymmetrical deglutition is observed an imbalance of the tonus of the left and right neck muscles should be kept in mind.

5. Tertiary contractions are observed frequently in normal individuals of higher ages.

6. Functional diverticula are rather rare phenomena, observed exclusively in patients with organic lesions of the pharynx, esophagus or other parts of the digestive tract.

ACKNOWLEDGMENT

The authors would like to express their appreciation to Dr Roger C. Breslau United States Air Force Hospital Tachikawa for his careful review of the manuscript.

INTRODUCTION

Since 1931 when the electron microscope was first employed for otologic investigation a wealth of information concerning the fine structure of the inner ear has become available. Outstanding contributions have been made by Carlström and Engström (1933), Engström (1931), Engström and Wersäll (1933*a*, 1933*b*, 1938*a* and 1938*b*), Engström and Sjöstrand (1934), Friedmann (1939 and 1962), Iurato (1961 and 1967), Iurato and de Petris (1967), Smith (1936, 1937 and 1961), Smith and Sjöstrand (1961), Hilding (1963), Kimura (1966), Kimura, Schucknecht and Sando (1964), Duvall, Flock and Wersäll (1966) and Spoendlin (1964 and 1966) as well as others.

A surface preparation technique using osmium fixed temporal bones, recently employed in the light microscope investigation of the inner ear (Engström, Ades and Andersson, 1966; Johansson and Hawkins, 1967*a* and 1967*b*) has added a new dimension to otological research. These studies, however, have been limited by the resolving power of the light microscope. An improved instrument with higher resolving power than that of the conventional microscope was desirable for investigation of surface preparations.

A new type of microscope—a scanning electron microscope (SEM)—which has been widely used in metallurgical investigations is now available for biomedical research. Unlike the conventional electron microscope which transmits an electron beam through the specimen, the image in the scanning microscope is created by secondary electrons emitted from the excited surface of the specimen. The result is a picture similar to the image produced on a television screen, a cathode ray tube. The depth of field obtained with the scanning microscope is about 500 times that of a light microscope. The magnification ranges between $\times 20$ and $\times 20\,000$ with a resolving power of $100\text{ }\mu$.

During the last several years, biological specimens studied with this new microscope have included such diverse material as cultured cells, human chromosomes, cell organelles, skeletal material, blood cells, and cancer cells, (Hovav, 1968). This paper reports on the efforts of the authors to study the general surface architecture of the cochlea and vestibular sensory organs of guinea pigs using the scanning electron microscope.

INTRODUCTION

Since 1931 when the electron microscope was first employed for otologic investigation, a wealth of information concerning the fine structure of the inner ear has become available. Outstanding contributions have been made by Carlström and Engström (1935), Engström (1951), Engström and Wersäll (1953a, 1953b, 1958a and 1958b), Engström and Sjöstrand (1954), Friedmann (1959 and 1962), Iurato (1961 and 1967), Iurato and de Petris (1967), Smith (1956, 1957 and 1961), Smith and Sjöstrand (1961), Hilding (1965), Kimura (1966), Kimura, Schucknecht and Sando (1964), Duvall, Flock and Wersäll (1966), and Sponendlin (1964 and 1966) as well as others.

A surface preparation technique using osmium-fixed temporal bone, recently employed in the light microscopic investigation of the inner ear (Engström, Aden and Andersson, 1966; Johansson and Hawkins, 1967a and 1967b) has added a new dimension to otological research. These studies, however, have been limited by the resolving power of the light microscope. An improved instrument with higher resolving power than that of the conventional microscope was desirable for investigation of surface preparations.

A new type of microscope—a scanning electron microscope (SEM)—which has been widely used in metallurgical investigations is now available for biomedical research. Unlike the conventional electron microscope which transmits an electron beam through the specimen, the image in the scanning microscope is created by secondary electrons emitted from the excited surface of the specimen. The result is a picture similar to the image produced on a television screen or cathode ray tube. The depth of field obtained with the scanning microscope is about 500 times that of a light microscope. The magnification ranges between $\times 20$ and $\times 20,000$ with a resolving power of 100 Å.

During the last several years, biological specimens studied with this new microscope have included such diverse material as cultured cells, human chromosomes, cell organelles, skeletal material, blood cells, and cancer cells, (Havens, 1968). This paper reports on the efforts of the authors to study the general surface architecture of the cochlea and vestibular sensory organs of guinea pigs using the scanning electron microscope.

MATERIAL AND METHODS

Ten young guinea pigs weighing between 300 and 400 grams were used in this study. Their temporal bones were removed immediately after sacrifice and fixed for one hour in phosphate-buffered osmic acid. The bones were rinsed thoroughly with Ringer's solution and then a graded alcoholic dehydration was carried out. The bony shell of the cochlea was removed with the aid of a surgical microscope at the stage of 70 alcohol. Each of the separated portions of the membranous cochlea and the vestibular organs were mounted on the aluminum microscope stage with Aquadag (carbon suspension in alcohol) and coated with gold. The gold coating provided a conductive surface on the otherwise non-conductive specimen. All of the important areas were photographed and examined stereoscopically, thereby providing a three dimensional appreciation of the structural morphology. A limited number of osmium fixed specimens of the vestibular sensory organs were treated with 10% hydrochloric acid for one to five minutes and then thoroughly washed with distilled water. This treatment dissolves the gelatinous otolithic membrane covering the sensory epithelium and uncovers the hairs of the sensory cells.

FINDINGS

A Cochlea (Figs 1 and 2)

Stria vascularis and its adjacent structures

A complex vascular network can be clearly appreciated in the stria vascularis. The vessels continue freely from the scala vestibuli area into the stria vascularis (Fig. 3). Epithelial cells covering the stria vascularis were equiaxed and hexagonal. Small depressions and numerous microvilli were noted on the epithelial surface of the stria vascularis (Fig. 4). These microdepressions were interpreted as microvesicles of the epithelial cells. Occasionally nuclei and intracellular inclusions were shown as well rounded protrusions. The size and shape of the epithelial cells of the stria vascularis was interrupted suddenly at the attachment of Reissner's membrane. This regular cellular arrangement observed in the stria vascularis was less pronounced in the epithelial cells lining the scala vestibuli.

The cellular arrangements of the spiral prominence were of great interest. Cells covering the upper margins of the spiral prominence were elongated hexagons with their long axis parallel to the plane of the basilar membrane (Fig. 5). The cells covering the central portion of the prominence were smaller equiaxed hexagons than those observed in the stria

Fig. 1 A schematic diagram illustrating how the cochlea was prepared. Reissner's membrane was removed to expose the underlying structures. The stria vascularis and its adjacent structures were separated from the temporal bone. The tectorial membrane was partially or totally removed. (Drawing by B. Eiter)

Fig. 2 A photomicrograph of the cochlea indicating areas studied. 1 stria vascularis and its adjacent structure; 2, spiral limbus; 3, tectorial membrane; 4, organ of Corti; 5, myelinated nerve fibers of the osseous spiral lamina.

Fig. 3. A scanning photomicrograph showing the entire stria vascularis and its adjacent structures. Arrows indicate the longitudinal course of spiral prominence in the stria vascularis. *R* Reissner's membrane insertions. *P* spiral prominence. *OS* outer sulcus cells. *ST* scala tympani.

vascularis. The size of the epithelial cells covering the lower margin of the prominence became larger, and at the margin of the outer sulcus cells the hexagonal cell surface could no longer be distinguished (Fig. 6). This cell arrangement was noticed in all of the four turns except at the blind ends of the cochlear duct where the spiral prominence faded away.

Cells covering the scala vestibuli and scala tympani were also examined. The surfaces of these cells were hexagonal but their margins were much less distinct than that found in the stria vascularis. Some areas revealed a mesh-like fibrous arrangement immediately under a thin layer of epithelial cells (Fig. 7 A and B). The mesh-like structure was interpreted as the spiral ligament.

Fig. 4. A high magnification of epithelial cell of the stria vascularis. Observe the microdepression on the cell surface (arrow) which are interpreted the vesicles of the electron microscope find. g. The small pediculated small structures are microvilli.

Litobus spiralis

The limbus spiralis was studied in order to discover how the tectorial membrane was attached. The cell arrangement in this region was not clear except in a few instances where the tectorial membrane attachment was extremely thin. In a few instances, depression similar to volcanic craters were observed. Sometimes, these structures were oriented parallel to the line of the cellular lip where the tectorial membrane contacts the limbus and they seemed to be more pronounced in the apical turn than in the basal turn (Fig. 8A and B). These craters varied considerably from one animal to another. When plastic embedded sections were examined by phase contrast and electron microscopes, it was clearly demonstrated that the crater formation showed different stages of development and was outlined by interdental cell membranes. The interdental cell membrane forming the craters revealed well developed microvilli. The opening of the crater to the endolymphatic space sometimes contained a residue of tectorial-membrane substance (Fig. 9).

Fig 19 (A) A scanning photomicrograph of thin-lamated nerve fibers observed near the habenula perforata. The myelin sheath resembles a bundle of microtubules. The diameter of the nerve fiber probably has increased during the center portion. (B) A lectro-micrograph of the myelinated nerve fibers from the same area.

Fig. 20. A schematic drawing of the macula illustrating the relationship between the otolithic membrane and the sensory epithelium. (The drawing is modified from I ratio, 1967 *Submicroscopic Structure of the Inner Ear Pergamon Press, London*. Drawn by B. Eiler after A. Bertolozzi.)

The three rows of hairs of the outer sensory cells were arranged in a "V" shape (Fig. 15 A and B). The hairs of the inner sensory cell were oriented in the same way as the outer hair cells but the "V" was less sharp. The head plate of the inner pillar and phalangeal process of the outer pillar were also identified and are shown in Fig. 16. A definite fibrillar arrangement was observed. The phalangeal processes of the Deiters cells showed irregular surfaces. Hensen's cells always seemed to be dried out leaving distinct grape-like lipid granules in their cytoplasm (Fig. 17 A and B). The cell boundaries of inner sulcus cells were not very distinct but the cell surface possessed abundant microvilli (Fig. 18).

Myelinated nerve fibers

Myelinated nerve fibers located in the osseous spiral lamina were frequently observed in specimens where this structure had been fractured accidentally. The myelinated nerve fibers appeared like uncarated wood with the central space empty (Fig. 19). This appearance was presumably a result of the drying and shrinking effect on delicate neural tissue while the tough myelin sheath was preserved.

B Vestibular Organs

Saccul and utricle (Fig. 20)

Macroscopically the sacculus resembled the shape of an "L" and the utricle resembled an opened shell. The mottled line of Engström (Johnson and Hawkins, 1967 b) could be observed in both the utricle and sacculus. The length of the otocysts varied between 0.5 micron and 170 microns. The otocysts appeared cylindrical with both ends sharply angu-

Fig 10 (A) A scanning photomicrograph of the myelinated nerve fibers observed in the habenular plexus. The myelin sheath resembles a bundle of myelin. The internal contents of the nerve fiber probably have shrunk during the drying process. (B) An electron micrograph of the myelinated nerve fibers from the same area.

Fig. 22. The scanning photomicrograph shows the otoconia embedded in the gelatinous substance.

lated. The cylindrical portion of some otoconia were also slightly angulated but the angulation was not continuous over the entire body of the otoconia (Fig. 21 A and B). The surfaces of most of the crystals were smooth but in some cases they were covered with a gelatin-like substance (Fig. 22). Occasionally a lamellar structure was seen on the side of the cylinder but this probably was another artifact (Fig. 21 C). Our data suggests that these crystals are partially or totally embedded in gelatin.

The distribution of different sizes of crystals could not be distinguished with certainty from our material but the finer crystals seemed to be located on the surface and peripheral margins of the otolith membrane whereas the larger crystals were situated in the deep center portion of the membrane (Figs. 23 A and B, 24 A and B).

Fig 21 (A) A scanning photomicrograph of the otocilia from the utricle showing the difference between the small and large crystals. Observe the cylindrical form of the lateral surface of the otocilia. (B) One of the crystals showing a typical cylindrical form. (C) Occasionally a dark band can be observed in the middle of the crystal.

Fig. 22. The scanning photomicrograph shows the otoconi embedded in the gelatinous substance.

lated. The cylindrical portion of some otoconia were also slightly angulated, but the angulation was not continuous over the entire body of the otoconi (Fig. 21 A and B). The surfaces of most of the crystals were smooth but in some cases they were covered with a gelatin like substance (Fig. 22). Occasionally a band-like structure was seen on the side of the cylinder but this probably was another artifact (Fig. 21 C). Our data suggests that these crystals are partially or totally embedded in gelatin.

The distribution of different sizes of crystals could not be distinguished with certainty from our material but the finer crystals seemed to be located on the surface and peripheral margins of the otolithic membrane whereas the larger crystals were situated in the deep center portion of the membrane (Figs. 23 A and B, 24 A and B).

Fig. 21. (A) A scanning photoelectron micrograph of the top surface of the crystal showing the difference between the main flat surface and the edge. (B) On the edge of the crystal showing a typical cylindrical form. (C) Occasionally a flat band can be observed. It is a row.

Fig. 22. The scanning photomicrograph shows the otoconia embedded in the gelatinous substance.

lated. The cylindrical portion of some otoconia were also slightly angulated, but the angulation was not continuous over the entire body of the otoconia (Fig. 21 A and B). The surfaces of most of the crystals were smooth but in some cases they were covered with a gelatin like substance (Fig. 22). Occasionally a band-like structure was seen on the side of the cylinder but this probably was another artifact (Fig. 21 C). Our data suggests that these crystals are partially or totally embedded in gelatin.

The distribution of different sizes of crystals could not be distinguished with certainty from our material but the finer crystals seemed to be located on the surface and peripheral margins of the otolithic membrane whereas the larger crystals were situated in the deep center portion of the membrane (Figs. 23 A and B, 24 A and B).

Fig. 2. (A) A phase-contrast micrograph of the saccule illustrating the reticuli-hip between otoclia and the sensory epithelium. (B) A scanning photomicrograph of the saccule showing the margin of the tili membrane. The adjacent supporting cell near the margin shows irregular cell structure.

Fig. 24. (A) A phase contrast micrograph of the utricle illustrating the relationship between the sensory epithelium and the utricle. (B) The same area as A, viewed by SEM. The snow drift line of Engström is clearly seen. The distribution of the different sizes of the otoconia can be observed. The marginal epithelium near the otolithic membrane appears smooth.

Fig. 25 (A) A surface scan image micrograph of the utricle showing abundant bodies of sensory-cell hairs (S). The otolith membrane was digested with acid. The epithelial cells nearest to the margin (A) of the sensory epithelium were smaller than those of the distal area (B). (B) A phase contrast micrograph of the same area. S: Sensory epithelium. A: epithelium nearest to the margin of the sensory epithelium. B: epithelium furthest from the sensory cell epithelium.

Fig. 24. (A) A scanning photomicrograph of sensory hair of the utricle illustrating their arrangement. (B) A higher magnification of few bundles of sensory hairs showing "church pipe-organ" arrangement. The inset is an electron microscopic photograph of the same area. The arrow indicates the kinocilium. Background crystals are artifacts resulting from the acid digestion.

Fig 23 (A) A survey scanning micrograph of the utricle showing abundant bundles of sensory-cell hairs (S). The otolithic membrane was digested with acid. The epithelial cell nearest to the margin (A) of the sensory epithelium were smaller than that of the distal area (B). (B) A phase contrast micrograph of the same area. S Sensory epithelium, A epithelium nearest to the margin of the sensory epithelium, B epithelium furthest from the sensory cell epithelium.

Fig. 26. (A) A scanning photomicrograph of sensory hair of the utricle illustrating their arrangement. (B) A higher magnification of few bundles of sensory hairs showing "church pipe-organ" arrangement. The insert is an electron microscopic photograph of the same area. The arrow indicates the lipocillium. Background crystals are artifacts resulting from the acid digestion.

Fig. 27 (A) A scanning photomicrograph of the wall in the same area showing internal cell wall margins. Some of the protrusions are possible nuclei of the cells. (B) A cell junction of the same area. Fig. A illustrates stratified double membrane.

Fig. 22 (A) A survey micrograph of the crista ampullaris which resembles a saddle. Both end of the saddle where the pit (an semilunar) is located, are shortened; artifact. The sensory epithelium is not clearly demonstrated here as of the strong distortions of the gelatinous substance (B) A phase contrast micrograph of the crista ampullaris for comparison.

When the otolithic membrane was removed the hairs of the sensory cells were exposed showing the typical hair arrangement of vestibular sensory cells (Fig. 25 A and B). Six or seven rows of hairs graduated in length and caliber resembling organ pipes were observed on a sensory cell. Each row contained 10 to 11 hairs. The hair cell arrangements definitely were directional (Fig. 26 A and B).

The supporting cells found between the sensory cells showed rather rough surfaces probably due to abundant microvilli. These supporting cells adjacent to the sensory epithelium covered by otolithic membrane were hexagonal. They possessed a rough cytoplasmic membrane as a result of a protrusion of cytoplasmic inclusions and nuclei (Fig. 27 A and B).

Crista ampullaris

Technical problems in the preparation of the specimens prohibited the observation of the arrangement of the hairs of sensory cells. The planum semilunatum was outlined by hexagonal cells containing numerous cytoplasmic inclusions. The neural epithelium gives the appearance of a saddle (Fig. 28 A and B).

DISCUSSION

Submerged interdental cells were first described by Voldrich (1907) who demonstrated the secretory activities of these cells. The observations of the similar structures to those described by Voldrich was also made by the authors using phase contrast and electron microscopy. His report concerning the distribution of these submerged cells agrees with our observation that these cells are more commonly found in the apical turn than in the lower turn. This finding was supposedly made in the normal guinea pig limbus area. Electron microscopic examination clearly shows that this dilated space is lined by the cell membrane of one or two interdental cells and that the cell surface is studded with microvilli. Various stages of crater formation were seen suggesting that we were observing the cells in several different physiological states. In another study by one of the authors (Lim) which dealt with the enzyme DPNH-diphosphorase, different states of the enzyme activities in these cells also were demonstrated. In the most advanced form the interdental cell resembled a goblet with the narrow ostium opening into the endolymphatic space. Occasionally a small amount of residue of a tectorial membrane-like substance clogged the ostium. Scanning electron microscopy verified the above observation suggesting the possibility of free communication of endolymph between this space in the interdental cells and outer scala media. The physiologic meaning of this structure is not yet clearly understood although, it is quite reasonable to assume that this structure is concerned with fluid dynamics of endolymph.

The less clearly defined cellular arrangement of epithelial cells lining the

scala vestibuli adjacent to Reissner's membrane insertion was in contrast with the well arranged epithellum of the cochlea. The DPXH-diaphorase study mentioned earlier always indicated high enzyme activity in the scala vestibuli suggesting an active participation in energy transport which may be related to the fluid dynamics. Together with Borghesani's "vasculo-epithelial zone" (1957 and 1967) of the limbus near the attachment of Reissner's membrane, these irregularly arranged epithelial cells seem to support the hypothesis that this area could participate in the metabolite process between blood and endolymph.

Our finding of the fibrous arrangement of the tectorial membrane with the radial fibers arranged at about 30-40 degree angle slanting towards the apex of the cochlea agrees with the previous observations made by Hilding (1933) and Iurato (1967). The marginal portion of the outer tectorial membrane gives the appearance of a thickened band and agrees with previous electron microscopic observations of the cut section. This structure may be comparable to that described by Holmer (1927) de Vries (1949) and others as "Randfasernetz".

Occasionally we observed a wrinkled appearance of the tectorial membrane. The wrinkling effect added difficulty in interpreting the fiber arrangement in this area, but it suggests that these fibers are arranged longitudinally. The wrinkling of the tectorial membrane occurred only at the points of contact with other structures, the limbus spiralis, the area between the outer sulcus cells and the border cells, and the Hensen's cells. Originally we interpreted the wrinkles as an artifact, but in view of the close correspondence of the wrinkles with the points of contact of the tectorial membrane, these wrinkles may have anatomic significance.

The scanning electron microscopic examination revealed a distinct network of fibers on the upper surface of the tectorial membrane which might serve as a net holding the tectorial membrane intact.

The crystalline structure of the otoconia of the utricle and saccule was studied with the greatest interest. Carlström and Engström (1955) reported that these crystals are calcium carbonate in the form of calcite in mammals, birds and sharks, whereas, in amphibians and bony fish they consist of calcium carbonate in the form of aragonite and in the lamprey the crystals are calcium phosphate. More recently Iurato and de Petris (1967) constructed after studying the rat ear a paper model of an otolith based on the cleavage plane of calcite. According to them, the major axis of the crystal forms a hexagonal prism and its side shows clear angulation. In our material the long sides of the prism were not necessarily angulated but rather the crystals resembled a cylinder with both ends having sharp pointed surfaces. This finding was rather consistent in all of our material. The dynamics of the crystals of the otoconia will be discussed in detail in a separate paper (Lim and Lane). Our material indicated that the larger otoconia were in the deep center portion of the neural epithelium whereas, the smaller ones seemed to cover the outer surface and peripheral portion

When the otolithic membrane was removed the hairs of the sensory cells were exposed showing the typical hair arrangement of vestibular sensory cells (Fig. 25 A and B). Six or seven rows of hairs graduated in length and caliber resembling organ pipes were observed on a sensory cell. Each row contained 10 to 11 hairs. The hair cell arrangements definitely were directional (Fig. 26 A and B).

The supporting cells found between the sensory cells showed rather rough surfaces probably due to abundant microvilli. These supporting cells adjacent to the sensory epithelium covered by otolithic membrane were hexagonal. They possessed a rough cytoplasmic membrane as a result of a protrusion of cytoplasmic inclusions and nuclei (Fig. 27 A and B).

Crista ampullaris

Technical problems in the preparation of the specimens prohibited the observation of the arrangement of the hairs of sensory cells. The planum semilunatum was outlined by hexagonal cells containing numerous cytoplasmic inclusions. The neural epithelium gives the appearance of a saddle (Fig. 28 A and B).

of the neural epithellum. The "snow drift lines of Engström" (Johnsson and Hawkins, 1967 b) of both utricle and saccule were also observed in our material. Our findings favor the hypothesis that the otoconia are embedded in gelatin rather than that the otoconia just makes contact with the surface of the gel as stated by Johnsson and Hawkins (1967 a and 1967 b). Occasionally a double band was found on the cylindrical side of crystals and this may suggest the level to which the otoconia were embedded in the gelatin.

The arrangement of the sensory-cell hairs of the cochlea and vestibule is in close agreement with the phase contrast microscope and electron microscopic findings. It was noted that the shape of the hairs of the inner and outer hair cells resembled a baseball bat with the handle side attached to the cuticular plate. The hairs of vestibular sensory organs resembled a church pipeorgan arrangement: the longest hair oriented towards the kinocilium. The surface of those hairs was smooth and occasionally they were bent. It must be mentioned that the removal of the otolithic membrane by means of acid digestion was essential to uncover the surface of the vestibular sensory cells.

This study demonstrates that the application of the scanning electron microscope in the examination of the inner ear structure is quite possible. The scanning electron microscope provided clear three dimensional information of the inner ear cell structures of higher resolution and greater depths of field than that provided by other currently available microscopes. Adding this new perspective of the inner ear structure which is already complicated by various cells in three dimension, we made a start towards a comprehensive gathering of information with greater resolving power. Such an evaluation is an important part of any attempt to understand the meaning of the more common two dimensional observation of microstructures of the inner ear. However, it must be mentioned that the satisfactory preservation of such fragile structures as Reissner's membrane, Hensen's and Claudius cells in the organ of Corti, for the SEM technique still remains to be improved. The proper interpretation may require years of accumulation of knowledge and continuing efforts in improving the technique and instrumentation.

SUMMARY AND CONCLUSION

The surface architecture of the inner ear was studied employing the scanning electron microscope. This instrument gives a three dimensional appreciation of a thick membranous structure which could not be studied with phase contrast microscopy. Such structures include the stria vascularis, limbus spiralis, otoconia and vestibular sensory epithellum. The major problem with this technique is the proper preservation of the fragile membranous structures.

INTRODUCTION

Anatomical data on the course and central termination of primary vestibular neurons from specific endorgans are essential for the proper design and interpretation of electrophysiological investigation of this neuron. The purpose of this study is to provide such information.

REVIEW OF LITERATURE

The basic manner in which primary vestibular neurons coursed on entering the brainstem was described by early neuronanatomists (Hoeffer 1891, Held, 1892, Cajal, 1909). According to these descriptions each vestibular fiber bifurcated within the brainstem into an ascending and a descending branch. The ascending branches supplied the superior vestibular nucleus and part of the lateral vestibular nucleus, while the descending branches comprised the descending vestibular root and gave off collaterals to the descending and medial vestibular nuclei. No correlation of certain fibers with the different vestibular endorgans was given in these or other less extensive reports on the vestibular nerve (Marlin, 1894, Sabón 1897, Winkler 1909, Sachs and Alvis, 1921, Gray 1926).

Two later reports have supplied significant information on the central projection of primary vestibular fibers. The first was that of Lorente de Nó (1933) wherein a thorough description was given of the course and termination of various classes (five) of fibers from the cat and mouse labyrinth as depicted by the Golgi method in normal young animals. He suggested that fiber groups I and II, consisting of small and large fibers, respectively represented all the semicircular canal with no differential localization of separate canals. Group IV and possibly Group III projected from the utricular macula while Group V represented saccular fibers. Although it is difficult because of nomenclature to identify the precise boundaries of his vestibular nuclei, it is apparent that Lorente de Nó also pointed out that only part of some vestibular nuclei received primary vestibular afferents (e.g. central Deltaria). He however did not include smaller cell groups such as the interstitial nucleus of the vestibular nerve and groups x, r, or z of Brodal. His study represents the earliest attempt to correlate the inner values of specific vestibular endorgans with different areas of termination in the brainstem.

INTRODUCTION

Anatomical data on the course and central termination of primary vestibular neurons from specific endorgans are essential for the proper design and interpretation of electrophysiological investigation of this neuron. The purpose of this study is to provide such information.

REVIEW OF LITERATURE

The basic manner in which primary vestibular neurons coursed on entering the brainstem was described by early neuroanatomists (Koelliker 1891, Held, 1892, Cajal, 1909). According to these descriptions each vestibular fiber bifurcated within the brainstem into an ascending and a descending branch. The ascending branches supplied the superior vestibular nucleus and part of the lateral vestibular nucleus, while the descending branches comprised the descending vestibular root and gave off collaterals to the descending and medial vestibular nuclei. No correlation of certain fibers with the different vestibular endorgans was given in these or other less extensive reports on the vestibular nerve (Martin, 1894, Sabin, 1897, Winkler 1909, Sachs and Alila, 1921, Gray 1926).

Two later reports have supplied significant information on the central projection of primary vestibular fibers. The first was that of Lorente de Nó (1933) wherein a thorough description was given of the course and termination of various classes (five) of fibers from the cat and mouse labyrinth as depicted by the Golgi method in normal young animals. He suggested that fiber groups I and II, consisting of small and large fibers, respectively, represented all the semicircular canals with no differential localization of separate canals. Group IV and possibly Group III projected from the utricular macula while Group V represented saccular fibers. Although it is difficult because of nomenclature to identify the precise boundaries of his vestibular nuclei, it is apparent that Lorente de Nó also pointed out that only parts of some vestibular nuclei received primary vestibular afferents (e.g., ventral Deltans). He however did not include smaller cell groups such as the interstitial nucleus of the vestibular nerve and groups x, y or z (Broadbent). This study represents the earliest attempt to correlate the innervation of specific vestibular endorgans with different areas of termination in the brain stem.

A second study of importance was that of Wallberg, Bowsher & Brodal (1958). On the basis of central degeneration resulting from complete section of the vestibular nerve via a labyrinthine approach these authors described the manner in which vestibular afferents terminated in the vestibular nuclei. Both the Nauta and Cleeves silver methods were used after appropriate survival times to allow for wallerian degeneration. They concluded that primary vestibular fibers reach all four vestibular nuclei and cerebellum but that in all of them certain regions were free of vestibular afferents. In the lateral vestibular nucleus, the fibers reached only the rostroventral regions; in the superior nucleus they terminated mainly in the central portion; in the medial nucleus they ended chiefly in the lateral parts; in the descending nucleus all except the rostrolateral region received primary vestibular fibers. They also confirmed the fact that primary afferents terminated in the interstitial nucleus of the vestibular nerve, a point which was made by Cajal (1909) but not mentioned either in a negative or positive way by Lorente de N6 (1933). No attempt was made to identify degeneration from specific endorgans.

A more recent report (Stein & Carpenter 1967) on the central projection of the vestibular endorgans in the monkey has utilized basically the same method employed in the present study. They demonstrated the central degeneration from lesions in different areas of Scarpa's ganglion which supply the vestibular endorgans. Relatively long (11-14 days) survival times were allowed for wallerian degeneration. No attempt will be made here to review all of their findings but certain projections were startling enough to warrant brief mention. One was the demonstration that the maculae (both utricle and saccule) projected to the superior vestibular nucleus in addition to the medial and descending nuclei. This was in contrast to previous reports and the present one. A second was that separate distinct projections from Scarpa's ganglion centrally could be described for the superior and horizontal canal cristinae. A third was that all vestibular endorgans have connections with the interstitial nucleus of the vestibular root. These will be discussed in this report.

It is clear that convincing information on the primary neuron projection from individual vestibular endorgans must be obtained by utilizing the experimental neuronal degeneration techniques. Similar information on the auditory bipolar neuron showing the different localization in the nerve and cochlear nucleus of fibers from different turns of the cochlea, has already been obtained with methods utilizing wallerian degeneration from lesions in the spiral ganglion (Rasmussen *et al.*, 1958) or demonstrating retrograde degeneration from lesions involving the sense organs (Sando, 1965). The reasons for the relative ease of obtaining such data on the auditory neuron are (1) the surgical accessibility of the cochlea and spiral ganglion in animals for creating lesions in these areas, and (2) the fact that the auditory bipolar neuron will undergo retrograde degeneration regularly after an end organ lesion that is severe enough to injure its dendrite.

Anatomical data on the primary vestibular neuron is more difficult to obtain, because in contrast to the auditory neuron, the vestibular bipolar neuron will not degenerate even following complete surgical destruction of the endorgan. In the present study the data were obtained by creating small lesions in Scarpa's ganglion which lies in the distal portion of the internal auditory canal. The resulting wallerian degeneration of the peripheral axon (dendrite) was traced out to the endorgan and correlated with the degeneration of the central axon in the vestibular nuclei. In this way small numbers of primary vestibular neurons can be studied by the experimental neuron degeneration technique.

NORMAL ANATOMY AND CONTROL ANIMALS

Certain prerequisite information is essential to this experimental study. This includes (1) the detailed anatomy of Scarpa's ganglion and of the vestibular nerve and its branches (2) the limits and architecture of the vestibular nuclei and (3) pattern and distribution in the vestibular nuclei of degeneration from retraction of the cerebellar flocculus necessary for surgical exposure of the internal auditory canal in the cat.

Normal Anatomy of the Vestibular Nerve and Branches

The Sudan Black technique (Rasmussen, 1961) was the method used to study the vestibular labyrinth. By this method, the entire nerve supply to the labyrinth enclosed in the petrous bone was stained in toto with Sudan Black B. The myelin sheaths of nerve fibers were colored dark blue. The non nervous tissues (bone and connective tissue) were easily decolorized without destaining the nervous tissue by using graded percentages of ethyl alcohol. The specimen was then decalcified with "Decal" requiring approximately 48-72 hours for complete decalcification of the cat petrous bone. With the aid of a Zeiss operating microscope the white decalcified bone was then carefully dissected away from the darkly stained nerves to the vestibular endorgans and cochlea using fine forceps on the specimen immersed in 10% formalin. The completed dissection revealed the entire membranous labyrinth with all its nerve supply intact.

The author has used this method to dissect and study the anatomy of the labyrinth of numerous species since 1955 (Rasmussen & Gacek). Approximately 400 normal cat ears have been studied in this manner and thorough familiarity gained of the detailed anatomy of the VIIIth nerve and its branches. Anatomical information was obtained from both intact and sectioned dissected specimens.

1. Careful examination of the specimen immersed in a liquid medium (10% formalin) using the dissection microscope was first used to study this anatomy.

A Initial examination of the intact specimen revealed the following (i) The peripheral vestibular nerve divided into a superior and inferior division. Each of these divisions further divided into nerve branches to the five classical vestibular endorgans—*superior division* superior canal crista, horizontal canal crista, utricular macula, anterosuperior part of saccular macula, *inferior division* posterior canal crista, saccular macula. (ii) The vestibular ganglion (Scarpa) which was comprised of cell bodies of the bipolar neurons that make up the vestibular nerve was a very compact, linear arranged cell mass that extended in a rostrocaudal direction. It was divided into two more or less distinct masses, the more rostral one being the part associated with the superior division and the more caudal one with the inferior division. It was furthermore evident that the ganglion of the superior division was arranged obliquely when viewed from a dorsal aspect, its rostral end lying more peripherally in the superior division than its caudal end (the end adjacent to the inferior division ganglion). The cells of the inferior division while remaining compact stretched out caudally over the cochlear nerve trunk as it passed ventral to the vestibular nerve and ganglion. (iii) Medial to the vestibular ganglion the nerve fibers of both vestibular divisions merged into a single vestibular nerve trunk which entered the brainstem.

B The individual nerve branches to each vestibular endorgan were traced back toward the nerve trunk by tensing them out with fine forceps. In this way useful information was obtained on the area of Scarpa's ganglion associated with each endorgan. (i) It was found that the fibers to the macular endorgans were associated with the ventral portions of Scarpa's ganglion. The portion supplying the utricular macula occupied the most ventral and caudal region of the superior division ganglion, the saccular ganglion was comprised of a mass of cells embedded in the main saccular nerve ventral to the posterior semicircular canal ganglion cells and adjacent to the cochlear nerve trunk. The proximal processes of the saccular ganglion were traced in a straight forward course ventral to the cells of the posterior canal fibers to form the most caudal fibers of the vestibular trunk. (ii) The fibers of the semicircular canal crista were associated with the dorsal portions of Scarpa's ganglion. Those to the superior and horizontal canals arose from a cell mass occupying the most rostral portion of the superior ganglion and another one of similar size which comprised the dorso-caudal region of the superior vestibular ganglion. This latter mass was positioned directly over the ganglion to the utricular macula. By dissection techniques, it was determined that each of the two ampullary nerves (superior and horizontal) was not associated with a distinct portion of the ganglion but that each of these nerve branches received approximately equal innervation from both cell masses concerned with semicircular canal innervation. It was as if these were not separate canal innervations but one canal nerve as far as the ganglion was concerned and one which split up peripherally to

Innervate two sensory areas. The ganglion cells innervating the posterior canal cristae were those of the inferior division which occupied the most dorsal portion of that mass and which extended caudally over the dorsal surface of the cochlear nerve. The dendrites of these cells formed the nerve to the posterior semicircular canal crista. The proximal axons of these cells arched rostromedially to join the incoming axons of the superior division canal ganglion cells in the rostral half of the vestibular nerve trunk (Fig. 43).

II Examination and reconstruction was done of serial horizontal and transverse sections of the vestibular nerve branches to the labyrinth.

The completely dissected specimens were thoroughly washed with distilled water and then placed in 5% and then 15% gelatin (in 37 C oven) for embedding. Under the operating microscope the specimens were oriented in the proper position with a fine needle as the gelatin hardened from cooling with ice cubes. In this way the specimen was embedded so as to obtain either horizontal sections parallel to the nerve fibers or transverse sections of the nerve fibers in the vestibular nerve and its branches. These sections were cut on a freezing microtome at 15 μ and serial sections taken and mounted in glycerin on slides.

A Reconstruction of horizontal serial sections was utilized to precisely define the location of ganglion cells and their processes. The general course of nerves to the vestibular endorgans was confirmed. In addition, it was determined that the proximal processes of the utricular ganglion cells coursed in a caudo-medial direction to occupy a position in the caudal one-third of the vestibular nerve just rostral to the fibers of the saccular nerve (Figs. 14-45).

It was also clearly seen that the axons of the ganglion cells innervating the posterior canal crista swung rostral to the utricular axons and joined the axons of the superior division canals in the rostral two-thirds of the vestibular nerve trunk (Figs. 14-4, 36A). Close examination further clarified the relationship of ganglion cells to the innervation of the superior and horizontal canal cristae. The dendrites from the rostral cell group of the superior division ganglion and those from the caudal-dorsal region of the ganglion merged to form each ampullary nerve to these canals (Fig. 36B). It also appeared that the rostral group of fibers were of much larger diameter than those of the caudal groups.

II Transverse sections of the vestibular nerve and branches were informative on the size and location of myelinated nerve fibers.

The most proximal sections taken through the vestibular nerve trunk just distal to the glial-schwann sheath junction showed the rostral portion of the nerve containing fibers from the three semicircular canals and a caudal part for fiber from the two maculae (Fig. 1).

A Initial examination of the intact specimen revealed the following (i) The peripheral vestibular nerve divided into a superior and inferior division. Each of these divisions further divided into nerve branches to the five classical vestibular endorgans—*superior division* superior canal crista, horizontal canal crista, utricular macula, anterosuperior part of saccular macula. *Inferior division* posterior canal crista, saccular macula. (ii) The vestibular ganglion (Scarpa) which was comprised of cell bodies of the bipolar neurons that make up the vestibular nerve, was a very compact, linear arranged cell mass that extended in a rostrocaudal direction. It was divided into two more or less distinct masses, the more rostral one being the part associated with the superior division and the more caudal one with the inferior division. It was furthermore evident that the ganglion of the superior division was arranged obliquely when viewed from a dorsal aspect. Its rostral end lying more peripherally in the superior division than its caudal end (the end adjacent to the inferior division ganglion). The cells of the inferior division while remaining compact stretched out caudally over the cochlear nerve trunk as it passed ventral to the vestibular nerve and ganglion. (iii) Medial to the vestibular ganglion the nerve fibers of both vestibular divisions merged into a single vestibular nerve trunk which entered the brainstem.

B The individual nerve branches to each vestibular endorgan were traced back toward the nerve trunk by teasing them out with fine forceps. In this way useful information was obtained on the area of Scarpa's ganglion associated with each endorgan. (i) It was found that the fibers to the macular endorgans were associated with the ventral portions of Scarpa's ganglion. The portion supplying the utricular macula occupied the most ventral and caudal region of the superior division ganglion. The saccular ganglion was comprised of a mass of cells embedded in the main saccular nerve ventral to the posterior semicircular canal ganglion cells and adjacent to the cochlear nerve trunk. The proximal processes of the saccular ganglion were traced in a straight forward course ventral to the cells of the posterior canal fibers to form the most caudal fibers of the vestibular trunk. (ii) The fibers of the semicircular canal cristae were associated with the dorsal portions of Scarpa's ganglion. Those to the superior and horizontal canals arose from a cell mass occupying the most rostral portion of the superior ganglion and another one of similar size which comprised the dorso-caudal region of the superior vestibular ganglion. This latter mass was positioned directly over the ganglion to the utricular macula. By dissection techniques, it was determined that each of the two ampullary nerves (superior and horizontal) was not associated with a distinct portion of the ganglion but that each of these nerve branches received approximately equal innervation from both cell masses concerned with semicircular canal innervation. It was as if these were not separate canal innervations but one canal nerve as far as the ganglion was concerned and one which split up peripherally to

innervate two sensory areas. The ganglion cells innervating the posterior canal cristae were those of the inferior division which occupied the most dorsal portion of that mass and which extended caudally over the dorsal surface of the cochlear nerve. The dendrites of these cells formed the nerve to the posterior semicircular canal crista. The proximal axons of these cells arched rostromedially to join the incoming axons of the superior division canal ganglion cells in the rostral half of the vestibular nerve trunk (Fig. 43)

II. Examination and reconstruction was done of serial horizontal and transverse sections of the vestibular nerve branches to the labyrinth

The completely dissected specimens were thoroughly washed with distilled water and then placed in 5% and then 15% gelatin (in 37 C oven) for embedding. Under the operating microscope the specimens were oriented in the proper position with a fine needle as the gelatin hardened from cooling with ice cubes. In this way the specimen was embedded so as to obtain either horizontal sections parallel to the nerve fibers or transverse sections of the nerve fibers in the vestibular nerve and its branches. These sections were cut on a freezing microtome at 15 μ and serial sections taken and mounted in glycerin on slides.

A Reconstruction of horizontal serial sections was utilized to precisely define the location of ganglion cells and their processes. The general course of nerves to the vestibular endorgans was confirmed. In addition, it was determined that the proximal processes of the utricular ganglion cells coursed in a caudo-medial direction to occupy a position in the caudal one third of the vestibular nerve just rostral to the fibers of the saccular nerve (Figs. 14-45)

It was also clearly seen that the axons of the ganglion cells innervating the posterior canal crista swung rostral to the utricular axons and joined the axons of the superior division canals in the rostral two-thirds of the vestibular nerve trunk (Figs. 14 & 36-4). Close examination further clarified the relationship of ganglion cells to the innervation of the superior and horizontal canal cristae. The dendrites from the rostral cell group of the superior division ganglion and those from the caudal-dorsal region of the ganglion merged to form each ampullary nerve to these canals (Fig. 36 B). It also appeared that the rostral group of fibers were of much larger diameter than those of the caudal groups.

D. Transverse sections of the vestibular nerve and branches were informative on the size and location of myelinated nerve fibers.

The most proximal sections taken through the vestibular nerve trunk just distal to the glial-schwann sheath junction showed the rostral portion of the nerve containing fibers from the three semicircular canals and a caudal portion for fibers from the two maculae (Fig. 1)

A Initial examination of the intact specimen revealed the following (i) The peripheral vestibular nerve divided into a superior and inferior division. Each of these divisions further divided into nerve branches to the five classical vestibular endorgans—superior division superior canal crista, horizontal canal crista, utricular macula, anterosuperior part of saccular macula, inferior division posterior canal crista, saccular macula (ii) The vestibular ganglion (Scarpa) which was comprised of cell bodies of the bipolar neurons that make up the vestibular nerve was a very compact, linear arranged cell mass that extended in a rostrocaudal direction. It was divided into two more or less distinct masses, the more rostral one being the part associated with the superior division and the more caudal one with the inferior division. It was furthermore evident that the ganglion of the superior division was arranged obliquely when viewed from a dorsal aspect, its rostral end lying more peripherally in the superior division than its caudal end (the end adjacent to the inferior division ganglion). The cells of the inferior division while remaining compact stretched out caudally over the cochlear nerve trunk as it passed ventral to the vestibular nerve and ganglion (iii) Medial to the vestibular ganglion, the nerve fibers of both vestibular divisions merged into a single vestibular nerve trunk which entered the brainstem.

B The individual nerve branches to each vestibular endorgan were traced back toward the nerve trunk by teasing them out with fine forceps. In this way useful information was obtained on the area of Scarpa's ganglion associated with each endorgan (i) It was found that the fibers to the macular endorgans were associated with the ventral portions of Scarpa's ganglion. The portion supplying the utricular macula occupied the most ventral and caudal region of the superior division ganglion, the saccular ganglion was comprised of a mass of cells embedded in the main saccular nerve ventral to the posterior semicircular canal ganglion cells and adjacent to the cochlear nerve trunk. The proximal processes of the saccular ganglion were traced in a straight forward course ventral to the cells of the posterior canal fibers to form the most caudal fibers of the vestibular trunk (ii) The fibers of the semicircular canal crista were associated with the dorsal portions of Scarpa's ganglion. Those to the superior and horizontal canals arose from a cell mass occupying the most rostral portion of the superior ganglion and another one of similar size which comprised the dorso-caudal region of the superior vestibular ganglion. This latter mass was positioned directly over the ganglion to the utricular macula. By dissection techniques, it was determined that each of the two ampullary nerves (superior and horizontal) was not associated with a distinct portion of the ganglion but that each of these nerve branches received approximately equal innervation from both cell masses concerned with semicircular canal innervation. It was as if these were not separate canal innervations but one canal nerve as far as the ganglion was concerned and one which split up peripherally to

Fig 1 Cross section of the vestibular nerve near the brainstem showing the rostral (R) and caudal (C) divisions. The facial and cochlear nerves and the internal auditory artery are identified for orientation. The squared area indicates location of Fig 2, 1 & 2. Sudan Black B stain.

It was apparent on close examination that the rostroventral part of the semicircular canal portion was occupied mainly by large diameter axons ($8-11 \mu$) while the caudo-dorsal part contained mainly smaller fibers ($3-5 \mu$) (Fig 2 A) proximal to the glial schwann sheath junction the small fibers covered the entire dorsal aspect of the large fiber group. As more peripheral sections through the superior division were viewed it was clear that the large axons belong to the rostral group of superior division ganglion cells and the smaller ones to the dorso-caudal group which overlie the utricular ganglion cells at this point (Fig 3). More peripheral sections through the two ampullary nerves of the superior division revealed that the smaller fibers encircled the larger ones until each ampullary nerve has a core of mainly large and a few small fibers and a peripheral zone of almost exclusively very small fibers (Fig 4 A). In terms of destination the core fibers were related to the crest or upper part of a crista while the peripheral fibers innervated the slopes. Fiber sizes in the posterior canal nerve displayed the same arrangement with larger fibers in the central portion and smaller fibers in the peripheral zone (Fig 4 B).

Examination of fiber diameters in the caudal division of the vestibular nerve revealed mainly fibers of the smaller diameter group with large ones scattered throughout (Fig 2 B). Fibers from the utricle occupied a rostral and ventral position in the caudal division of the vestibular trunk (Fig 1). As more lateral sections were viewed, the utricular axons passed ventral and rostral to the posterior canal axons to find their cell bodies in Scarpa's ganglion of the superior division. These utricular ganglion cells assumed the appearance of a separate ganglionic mass ventral to the cell bodies of the small fibers to the superior and horizontal canal cristae (Fig 3 A). The dendrites of these cells formed the utricular nerve which occupied the

ventral and caudal third of the superior vestibular division. The utricular nerve, comprised of mostly small fibers, split off peripheral to the ganglion and bent sharply in a caudal lateral direction to innervate the utricular macula.

Sacculus fibers were less numerous than any other vestibular branch (Cacek & Rasmussen 1961) and were also mainly small fibers with some large ones evenly scattered among the smaller ones. In the vestibular nerve they occupied the most caudal and dorsal position (Fig. 1). They coursed in a ventro lateral direction passing at a right angle to the arching posterior canal axons and ganglion cells, to find the sacculus ganglion cells. The ganglionic mass was easily identified by the presence of the vestibulo-cochlear (Oör) anastomosis (Fig. 34). The sacculus neuron in its entire peripheral course bore a close relationship to the cochlear nerve. Its nerve fibers paralleled those of the cochlear nerve.

Anatomy of Vestibular Nuclei

In the older literature much confusion existed because of differences in delineation of the classical vestibular nuclei. The report of Brodal & Lompelano (1957) has done much to clarify these boundaries and has provided the guideline for the interpretation of degeneration in the brainstem of the cat.

Thionine stained sections of normal cat brainstems and Nauta impregnated experimental brainstem sections which were counterstained with thionine were very helpful in recognizing the various nuclear groups and the morphology of the cells in these nuclei.

A brief review will be presented of the vestibular nuclei emphasizing features pertinent to the projection of the primary neurons.

Superior Vestibular Nucleus. The SVN was characterized by a population of medium and large neurons which occupied the central portion of the nucleus while the periphery contained small neurons (Fig. 5). These small cells appeared to outnumber the larger ones. Large fascicles of nerve fibers traveled up the central zone in a dorso-medial direction. The cells in the medial part of the nucleus were aligned horizontally in a laminar pattern.

Lateral Vestibular Nucleus. The rostro-ventral part of the LVN adjoined the caudal end of the SVN. The medium sized neurons here were characteristically arranged in rows extending medially from the incoming vestibular root. This arrangement reflected the direction of incoming fiber bundles from the vestibular root to the MVN which was adjacent to the fourth ventricle.

At caudal levels of the LVN a change occurred in the alignment of cells in the ventral division. The medium to large cells here were directed in an oblique dorsomedial direction from the vestibular root. The cells of the MVN at this level also were grouped into a dorsal one lined up with the

Fig. 5. *A*, Transverse section through the superior colliculus, nucleus, 20 \times , larger cell body = center of nucleus of small cells = the periphery Thionin method. *B*, High-power photomicrograph of *A* demonstrating the difference in cell size in the SVN.

cells of the LVN and a ventral one lined up with a lamina of smaller cells probably representing the most rostral limit of the DVN which blended in with the ventral LVN at this level.

The larger dorsal division of the LVN containing giant multipolar neurons, has been shown by others and by the present study to be devoid of incoming primary vestibular innervation. It is not described here.

Descending Vestibular Nucleus. At the level of the caudal portion of the vestibular root the rostral portion of the DVN became apparent and the ventral LVN was almost gone. Just caudal to the vestibular root the laminar arrangement of cells in the rostral DVN was evident. Cells belonging to the lateral part of this nucleus were scattered throughout the descending vestibular root; no primary vestibular fibers terminated these cells.

In the caudal region of the DVN and the MVN the most striking change

Fig 7 A Rostral division of the vestibular nucleus of the cat (NIV). Thionin method. B Caudal division of the NIV. Note the small size of this group. Thionin method.

was that the cells were more numerous and diffusely arranged. At this level both cerebellar and primary vestibular fibers ended diffusely in these nuclei.

At these caudal levels the small nucleus labeled group "v" by Brodal was seen (Fig. 6). It was a compact nucleus composed of mainly small cells with a few medium sized neurons scattered throughout the nucleus. This nucleus lay just dorsal to the restiform body and was interposed between the lateral limits of the LVN and medial limits of the dorsal cochlear nucleus. Many of the neurons were aligned so that their processes were directed toward the dorsal cochlear nucleus.

The interstitial nucleus of the vestibular nerve was carefully studied in serial sections (Fig. 7). This nucleus was regularly divided into two cell masses, one embedded in the most rostral fibers of the vestibular root and a more caudal one (smaller in size) in the middle portion of the vestibular root. This nucleus was composed of both small and medium sized neurons.

Cerebellar Degeneration from Retraction

It is well known that even the slightest compression of cerebellar or cerebral cortex will produce degeneration of neurons. Axons of these neurons will of course undergo wallerian degeneration and be demonstrated with the technique used here. Several investigators have demonstrated the cerebellar projections from both cortex and cerebellar nuclei onto the vestibular nuclei (Jansen & Brodal 1940; Walberg & Jansen 1961; Walberg *et al.* 1962; Thomas *et al.*, 1966).

In the cat it was decided that the best way to approach the vestibular ganglion for the purpose of making small discrete lesions was through the roof of the internal auditory canal. This required a posterior fossa craniotomy and retraction of the floccular lobe and surrounding cerebellum. The degeneration into the vestibular nuclear complex from this retraction was studied in a control group of six cats.

These six cats were operated upon in exactly the same manner as those experimental ones in which lesions were created in Scarpa's ganglion. The posterior fossa craniotomy was performed and the cerebellum retracted with a malleable metal strip retractor to expose the arcuate eminence and internal auditory meatus. A high speed dental drill was used to move the roof of the internal auditory canal from the meatus to as far rostral as was possible without damaging the superior petrous sinus. Bone removal was carried to a point where only a thin shelf of bone covered the internal auditory canal. The shelf was carefully removed piecemeal in an upward direction using small angled ear curettes to avoid damage to the nerves in the canal and also to avoid tearing or tension on the dural lining of the internal auditory canal. The intact dural covering of the vestibular and cochlear nerves was then carefully slit with a small knife and reflected aside to expose the ganglion and nerves of the superior and inferior vestibular divisions, and the cochlear nerve as it passed ventral to the inferior division. No lesion was made the dural flaps were replaced and the retractor was

Fig. 2. Transverse section through the lateral vestibular nucleus (LVN) and the medial vestibular nucleus (MVN) demonstrating the pattern of degeneration (arrow) from cerebellar retraction. Note the absence of degeneration in central part of the LVN and MVN and incoming vestibular root (VR).

removed allowing the cerebellum to re-expand into the cerebello-pontine angle. The wound was closed by approximating two muscle layers over the cranial defect. The approximate time for the procedure ranged from 1 to 1 1/2 hours.

The six control animals were not all operated on at the beginning of the experiment series; the operations were performed at more or less regular intervals throughout the period of 2 1/2 years. There did not appear to be any significant decrease in the amount of cerebellar degeneration in the more recently performed operations. However the amount of degeneration did vary from mild to fairly severe in different animals of this control group. The pattern of descending degeneration onto the vestibular complex was consistent.

The vestibular area of the brain stem in an animal showing the greatest degree of cerebellar degeneration will be described.

Superior Vestibular Nucleus Although some scattered degenerating fibers were seen distributed in the most dorsal and rostral regions of the SVN, most of the degenerating axons in this area were noted in fascicles descend-

was that the cells were more numerous and diffusely arranged. At this level both cerebellar and primary vestibular fibers ended diffusely in these nuclei.

At these caudal levels the small nucleus labeled group "v" by Brodal was seen (Fig. 6). It was a compact nucleus composed of mainly small cells with a few medium sized neurons scattered throughout the nucleus. This nucleus lay just dorsal to the restiform body and was interposed between the lateral limits of the LVN and medial limits of the dorsal cochlear nucleus; many of the neurons were aligned so that their processes were directed toward the dorsal cochlear nucleus.

The intersillial nucleus of the vestibular nerve was carefully studied in serial sections (Fig. 7). This nucleus was regularly divided into two cell masses, one embedded in the most rostral fibers of the vestibular root and a more caudal one (smaller in size) in the middle portion of the vestibular root. This nucleus was composed of both small and medium sized neurons.

Cerebellar Degeneration from Retraction

It is well known that even the slightest compression of cerebellar or cerebral cortex will produce degeneration of neurons. Axons of these neurons will of course undergo wallerian degeneration and be demonstrated with the technique used here. Several investigators have demonstrated the cerebellar projections from both cortex and cerebellar nuclei onto the vestibular nuclei (Janssen & Brodal 1940; Wallberg & Janssen 1961; Wallberg *et al.* 1962; Thomas *et al.* 1966).

In the cat it was decided that the best way to approach the vestibular ganglion for the purpose of making small discrete lesions was through the roof of the internal auditory canal. This required a posterior fossa craniotomy and retraction of the occipital lobe and surrounding cerebellum. The degeneration into the vestibular nuclear complex from this retraction was studied in a control group of six cats.

These six cats were operated upon in exactly the same manner as those experimental ones in which lesions were created in Scarpa's ganglion. The posterior fossa craniotomy was performed and the cerebellum retracted with a malleable metal strip retractor to expose the arcuate eminence and internal auditory meatus. A high speed dental drill was used to remove the roof of the internal auditory canal from the meatus to as far rostral as was possible without damaging the superior petrosal sinus. Bone removal was carried to a point where only a thin shelf of bone covered the internal auditory canal. The shelf was carefully removed piecemeal in an upward direction using small angled ear curettes to avoid damage to the nerves in the canal and also to avoid tearing or tension on the dural lining of the internal auditory canal. The intact dural covering of the vestibular and cochlear nerves was then carefully slit with a small knife and reflected aside to expose the ganglion and nerves of the superior and inferior vestibular divisions, and the cochlear nerve as it passed ventral to the inferior division. No lesion was made; the dural flaps were replaced and the retractor was

removed, allowing the cerebellum to re-expand into the cerebello-pontine angle. The wound was closed by approximating two muscle layers over the cranial defect. The approximate time for the procedure ranged from 1 to 1 1/2 hours.

The 14 control animals were not all operated on at the beginning of the experimental series; the operations were performed at more or less regular intervals throughout the period of 2 1/2 years. There did not appear to be any significant decrease in the amount of cerebellar degeneration in the more recently performed operations. However, the amount of degeneration did vary from mild to fairly severe in different animals of this control group. The pattern of descending degeneration onto the vestibular complex was consistent.

The vestibular root of the brain stem in an animal showing the greatest degree of cerebellar degeneration will be described.

Superior Vestibular Nucleus Although some scattered degenerating fibers were seen distributed in the most dorsal and rostral regions of the SVN, most of the degenerating axons in this area were noted in fascicles descend-

Fig 0 Transverse section through the caudal half of the MVN and the DVN. There are diffuse and generally cerebellar nerve fibers in these nuclei.

ing through the caudal and lateral portions of the nucleus. It is very possible that some of these end on cells in this part of the nucleus; however the medial and ventral portions were free of degenerating fibers.

Lateral Vestibular Nucleus At the junction of the superior and lateral nuclei many descending degenerating fibers were seen in a fascicular arrangement which did not appear to be terminating on cells in the rostro-ventral extension of the LVN but joined the greatest proportion of all the descending cerebellar degeneration to the dorsal division of the LVN (Fig 8). Abundant preterminal degeneration about the cells in this division was seen but none on the cells in the smaller ventral portion of the LVN. Some of the descending degeneration continued on in a ventral and caudal direction toward the DVN and the caudal regions of the MVN.

Descending (Inferior) Vestibular Nucleus In the rostral part of the DVN where some large and medium sized cells were present occasional preterminal degeneration was seen. This region by and large was free of degeneration in even the most severe degree of cerebellar degeneration.

However as the more caudal regions of both the DVN and the MVN were

Fig. 10 Vestibular root and interstitial nucleus in control animal. Note the absence of degeneration in the root and nucleus. Arrow indicates few normal fibers which are impregnated with silver.

examined, descending degeneration was present scattered throughout the cellular makeup of the nuclei (Fig. 9). Abundant preterminal and terminal degeneration was seen. Because of the widespread degeneration at these caudal levels, detailed evaluation of preterminal degeneration from primary afferent destroyed in experimental animal 1 was not possible.

Medial Vestibular Nucleus Rostral and midportions of this nucleus were free of degenerating cerebellar axons. However as described in previous sections, the more caudal area of the MVN along with the DVN were consistently covered with scattered degeneration and could not be precisely evaluated in the experimental animals.

Other Nuclei Both divisions of the NIV were consistently free of any degeneration (Fig. 10). Since it was of particular importance in the evaluation of experimental results, the small group of cells labeled group "Y" by Brodal was carefully looked for and examined. This group of small cells located between the lateral aspect of the LVN and partly overlying the reticular

Fig 9 Transverse section through the caudal half of the MVN and the DVN. There are diffuse degenerating cerebellar nerve fibers in these nuclei.

ing through the caudal and lateral portions of the nucleus. It is very possible that some of these end on cells in this part of the nucleus; however the medial and ventral portions were free of degenerating fibers.

Lateral Vestibular Nucleus At the junction of the superior and lateral nuclei many descending degenerating fibers were seen in a fascicular arrangement which did not appear to be terminating on cells in the rostro-ventral extension of the LVN but joined the greatest proportion of all the descending cerebellar degeneration to the dorsal division of the LVN (Fig 8). Abundant preterminal degeneration about the cells in this division was seen but none on the cells in the smaller ventral portion of the LVN. Some of the descending degeneration continued on in a ventral and caudal direction toward the DVN and the caudal regions of the MVN.

Descending (Inferior) Vestibular Nucleus In the rostral part of the DVN where some large and medium sized cells were present occasional preterminal degeneration was seen. This region by and large was free of degeneration in even the most severe degree of cerebellar degeneration.

However, as the more caudal regions of both the DVN and the MVN were

FIG. 12. A. Drawing of the surgical exposure of the internal auditory meatus before drilling away the petrous segment of the right temporal bone. B. Completed exposure of the culbulae (CN) and ganglion after removing the roof of the internal auditory canal.

occipital condyles. After slitting the dura over the cerebellum, the arachnoid membranes on the right side were teased away allowing for unrestrained retraction of the cerebellar flocculus and surrounding cerebellar lobe. This retraction was effected with a malleable metal strip which was inserted down along the superior surface of the petrous bone from the arcuate eminence medially. The flocculus was retracted gently from the subarcuate fossa until the internal auditory meatus was fully visualized with the VIII nerve emerging from it (Fig. 12 A).

The dense bone over the internal auditory canal and medial to the arcuate eminence was then removed with very small cutting burrs until only a thin plate of bone remained covering the nerves in the canal. This final shelf of bone was removed by using angled ear curettes and directing the curettage away from the nerves. The dural covering of the canal was then carefully cut and reflected aside (Fig. 12 B).

This exposure allowed visualization of the vestibular nerve from its emergence rostral-ventral to the cochlear nucleus out to a point 1-2 mm distant to Scarpa's ganglion. The region occupied by the ganglion was indicated by a narrow pink zone stretching obliquely transverse to the direction of the fibers in the superior division. The continuation of this zone (as the ganglion associated with the posterior canal fibers) could be followed arching caudally over the cochlear nerve trunk. The location of the ganglion was accentuated by the lighter appearance of the myelinated axons on either side of the ganglion.

Lesions were made only on the right side in each animal with the left ear and ganglion acting as control. These lesions in various parts of the ganglion were made with (a) a small (0.2 mm) unipolar electrode (2 milliamperes for 2 seconds), (b) a small knife or (c) a small needle. The dural

Fig 11 Group "neurons" in control animal with absence (degeneration) of the LVN, although there is abundant descending cerebellar degeneration passing through the LVN.

body was free of terminal degeneration despite the fact it was surrounded by abundant descending degeneration (Fig. 11).

Vestibular Root The value of this operative technique for exposing the vestibular ganglion in the internal auditory canal without damaging vestibular neurons was supported by the absence of degenerating axons in the vestibular root in these control animals (Fig. 10).

MATERIALS AND METHODS

Fifty-seven healthy young adult cats were used in this study. Aributal (70 mg/kg) was injected intraperitoneally to effect anesthesia. The scalp and posterior cervical skin areas were shaved and prepped surgically after the animal's head was secured in a flexed position with a head holder. The usual sterile precautions were adhered to during the operative procedure.

A posterior fossa craniotomy was performed carefully removing occipital bone from the occipital crest to the foramen magnum and laterally out to the

The same operation, including exposure of the nerves in the internal auditory canal except for the lesion in the ganglion was performed on six animals. These represented the control animals discussed previously.

The remaining 47 cats were processed as described. The peripheral lesion with resulting degeneration in the vestibular branches and in the vestibular nerve trunk was reconstructed from the Sudan Black stained sections of the labyrinth. This was correlated with the central axonal degeneration in the vestibular root and vestibular nuclear complex.

The Evaluation of Lesions in the Vestibular Ganglion (Scarpa) A crucial part in the evaluation of results in this study was the accurate determination of the extent of the lesion in the vestibular ganglion and the resulting degeneration in the vestibular branches. A short discussion of important factors that could influence this evaluation is appropriate at this point.

The primary vestibular neurons are true bipolar neurons whose peripheral processes (dendrites) comprise the nerve branches to the endorgans and whose central processes (axons) make up the vestibular nerve trunk. There are over 12,000 cell bodies of these neurons compactly arranged in the vestibular ganglion of the cat. A complete evaluation of the lesion includes not only the limits of the injured ganglion cells but also the number and distribution of the degenerating peripheral processes compared to the number and course of the degenerating central processes produced by the lesion. This can only be accomplished by very close examination and reconstruction of the serial sections of the vestibular nerve and branches. The most useful lesion is a small one limited to the ganglion which produces a number of degenerating fibers peripheral to the ganglion which is approximately equal to the number of degenerating axons central to it.

It was discovered after making several lesions in the ganglion with a small bipolar electrode that, even with little current, spread to surrounding areas was sufficient to cause degeneration of axonal processes of cells not included in the intended lesion. This was very misleading in determining accurately the vestibular endorgan that was supplied by the group of ganglion cells injured. Therefore the electrolytic method of producing small lesions in the ganglion was used only for very superficial lesions, and only a fine straight needle or small knife was used to produce consistently small discrete lesions deep in the ganglionic mass.

It has been pointed out by Rasmussen (1946) and others (Nageotte 1906; Sjökvist 1928) that Wallerian degeneration of nerve fibers distal to the glial-schwann sheath junction proceeds at a much faster rate than central to this zone. Rasmussen recommended reduction of the survival time in the cat from 10-14 days down to 5-7 days for optimal demonstration of degenerated peripheral segment of nerve fibers. He admonished that any experimental investigation in studying the demonstration of segments of degenerating fibers distal and proximal to the glial-schwann sheath zone must be designed to take into account the differential rates of degeneration

flap was replaced over the internal auditory canal a small piece of gelfoam laid in the bony defect over the canal and the posterior fossa craniotomy defect closed with two layers of muscle. The first layer of deep cervical and temporalis muscles were loosely approximated to allow for expansion of cerebellum from postoperative edema. The second layer of superficial cervical and scalp muscles was closely approximated with running chromic suture. The skin edges were finally closed with interrupted dermalon suture (000) and plastic spray-on dressing applied.

Postoperatively the animals were administered 10 cc of 5% glucose in water subcutaneously but no antibiotics were given to the animals in this series.

The animals were observed postoperatively only for gross nystagmus and ataxia with a magnifying lens. No attempt was made to record such findings with electronystagmography.

The animals were allowed to survive from 4 to 7 days to allow for wallerian degeneration. All cats were killed by intracardiac perfusion under general anesthesia according to the method of Koenig, Groat & Windle (1945). Three per cent potassium dichromate was added to the 10% formalin perfusion solution in accordance with Rasmussen's modification of the Nauta silver method which was used on the brainstem sections.

The animals were then decapitated and the calvarium and bony tentorium carefully removed. Dura was reflected over all exposed surfaces of brain and the heads immersed in 400-500 cc of 10% formalin for at least 48 hours before the brainstem and petrous bones were removed. This removal was performed under the operating microscope by carefully cutting the emerging cranial nerves of the brainstem without exerting tension on these nerves.

The brainstems and petrous bones were allowed further fixation by immersion for 36-48 hours. Brainstems were then trimmed to appropriate size and frozen sections cut at 30 μ . The Nauta silver method, as modified by Rasmussen, was then used to demonstrate axonal degeneration in the brainstem. Very close sections were made through the vestibular nuclear areas of each animal and reconstructed to evaluate the degeneration pattern resulting from the various lesions in Scarpa's ganglion.

The petrous bones were stained *in toto* with Sudan Black according to Rasmussen's technique. The vestibular complex of nerve branches was obtained by carefully dissecting away the decalcified bone under the dissecting microscope as described in the previous section on normal vestibular anatomy. These specimens were then embedded in 15% gelatin and serial frozen sections cut (15 μ) on a plane parallel to the superior and inferior division fibers. In this way degenerating fibers were optimally demonstrated in the nerve branches.

Of the 54 animals operated upon in this experiment four animals died in the first one to two days following surgery. Since there was no evidence of infection or hemorrhage it is possible that increased intracranial pressure possibly from edema was instrumental as the cause of death.

Fig. 12. Drawn x of the reconstructed lesion and degeneration pattern I. (Small 34. See Figs. 4 and 46 for label 1: tubular endorgans in the right and the external cell on the left).

cent to the rostral division of the Interstitial nucleus, abundant terminal degeneration was seen in this nucleus (Figs. 16, 17). These apparently represent collaterals from the incoming degenerating axons because the number of degenerating fibers on either side of the nucleus appeared equal.

At the dorsal aspect of the descending trigonular root, these degenerating axons bifurcated into an ascending and a descending branch. The ascending branch turned abruptly in a dorsomedial direction toward the central region of the SVN (Fig. 16). Long collaterals were seen emerging from these ascending branches in the ventral part of the nucleus (Fig. 18). There appeared to be only one collateral branch from each ascending fiber. These collaterals were seen swinging in a medial and then dorsal direction to approach medium-sized cells stretching across the medial half of the SVN toward the fourth ventricle. The most medial extent of this group of cells appeared to merge with the rostral end of the SVN. Rich preterminal degeneration was seen around these cells.

Beyond the take-off of collaterals, the ascending axons continued up the ventral region of the SVN in a dorsomedial direction and terminated on the large Golgi medium cell in this portion of the nucleus (Fig 19). The smaller cell peripheral zone of the nucleus was free of degeneration. It was not possible to determine whether these large degenerating axons continued up into the cerebellar area because of the presence of descending cerebellar degeneration in this area of the SVN.

The descending branches in the animal were seen as coarse degenerating fibers located in the most medial and ventral position in the descending vestibular root. As these fibers passed caudally in the root they could be seen crossing ventral to the normal incoming primary afferent axons of the vestibular root. In the caudal half of the ventral division of the LVN

in these two regions. Therefore survival time allowed for wallerian degeneration in this experiment ranged from 4 to 7 days.

The significance of this point was emphasized when lesions were placed in those parts of Scarpa's ganglion that gave rise to the smaller caliber fibers. It is well known that (1) small fibers degenerate faster than large ones and (2) the peripheral process of a bipolar cell is of smaller caliber than the central one. Therefore the distal processes of the ganglion cells in the small fiber population are indeed very small. If an animal with a lesion in this part of the ganglion were allowed to survive 10-14 days, the distal processes of the injured ganglion cells would have completely degenerated and could not be demonstrated histologically with the Sudan Black technique. This obviously would effect the evaluation of the degeneration pattern significantly.

OBSERVATIONS

The lesions and resulting peripheral and central degeneration in six animals will be presented in detail to demonstrate the projection from the vestibular endorgans. The results in remaining cats were used to confirm these lesions either by duplicating them exactly or by the inclusion of more than one sensory area's nerve supply. These will not be discussed in detail in this report.

SEMICIRCULAR CANALS

A Superior Division (Superior and horizontal canals)

Cat 6 (Fig. 13) In this animal a very small lesion was made with a straight pick directed into the rostral part of the ganglion of the superior vestibular division on the right. Postoperatively the animal demonstrated a gross horizontal rotatory nystagmus to the left which persisted for 3 days. The animal was perfused 5 days postoperatively.

(a) *Lesion and peripheral degeneration* Reconstruction of the lesion showed a very small area of destruction in the rostral part of Scarpa's ganglion (Fig. 14 A). Degenerated large-sized fibers coursed distally from the lesion and then diverged so that approximately half entered the nerve to the horizontal canal and half to the superior canal nerve. The degenerated fibers occupied a central position in the ampullary nerves (Fig. 14 B).

A compact bundle of degenerated axons was seen coursing centrally from the lesion in Scarpa's ganglion (Fig. 14 B). This bundle was located in the rostral region of the vestibular nerve trunk and remained in this location as the vestibular nerve became the vestibular root in the brainstem.

(b) *Central degeneration* Large degenerating axons were seen coursing in the most rostral part of the vestibular root. As these fibers passed adja-

Fig. 12 Drawing of the reconstructed lesion and degeneration pattern in the vestibular root. See Figs. 13 and 14 for label: mvn = medial vestibular nucleus; dvN = dorsal vestibular nucleus; hvN = horizontal vestibular nucleus. The right and left sides of the brain are indicated on the left.

cent of the rostral division of the interstitial nucleus, abundant terminal degeneration was seen in this nucleus (Figs. 16, 17). These apparently represent collaterals from the incoming degenerating axons because the number of degenerating fibers on either side of the nucleus appeared equal.

At the dorsal aspect of the descending trigeminal root, these degenerating axons bifurcated into an ascending and a descending branch. The ascending branches turned abruptly in a dorsomedial direction toward the central region of the SVN (Fig. 16). Long collaterals were seen emerging from these ascending branches in the ventral part of the nucleus (Fig. 18). There appeared to be only one collateral branch from each ascending fiber. These collaterals were seen winging in a medial and then dorsal direction to approach medium-sized cells stretching across the medial half of the SVN toward the fourth ventricle. The most medial extent of this group of cells appeared to merge with the rostral end of the SVN. Rich preterminal degeneration was seen around these cells.

Beyond the take-off of collaterals, the ascending axon continued up the central region of the SVN in a dorsomedial direction and terminated on the large and medium cells in this portion of the nucleus (Fig. 19). The smaller-celled peripheral zone of the nucleus was free of degeneration. It was not possible to determine whether these large degenerating axons continued up into the cerebellar area because of the presence of descending cerebellar degeneration in this area of the SVN.

The descending branches in this animal were seen as coarse degenerating fibers located in the most medial and ventral position in the descending vestibular root. As these fibers passed caudally in the root, they could be seen coursing ventral to the normal incoming primary afferent axons of the vestibular root. In the caudal half of the ventral division of the LVN,

In these two regions. Therefore survival time allowed for wallerian degeneration in this experiment ranged from 4 to 7 days.

The significance of this point was emphasized when lesions were placed in those parts of Scarpa's ganglion that gave rise to the smaller caliber fibers. It is well known that (1) small fibers degenerate faster than large ones and (2) the peripheral process of a bipolar cell is of smaller caliber than the central one. Therefore the distal processes of the ganglion cells in the small fiber population are indeed very small. If an animal with a lesion in this part of the ganglion were allowed to survive 10-14 days, the distal processes of the injured ganglion cells would have completely degenerated and could not be demonstrated histologically with the Sudan Black technique. This obviously would effect the evaluation of the degeneration pattern significantly.

OBSERVATIONS

collaterals could be seen taking off at right angles to these descending root fibers and passing obliquely across the LVN without terminating on any of the large or medium sized cells. These collaterals were directed toward the dorsal half of the MVN and were seen to terminate near cells in that part of the MVN and also around medium sized cells at the medial most region of the LVN.

As the degenerated descending rami were followed still more caudally in the descending vestibular root and reached levels of the rostral part of the DVN more collaterals were seen to arise and course in a directly medial direction. Preterminal degeneration was noted around some small and medium sized cells in the DVN but none around the large cells. Most of the collaterals passed through the dorsal acoustic atria and terminated in the ventral portion of the MVN. Here preterminal degeneration was seen in the lateral part of the nucleus.

In more caudal regions of the descending vestibular root the degenerating axons became more diffusely arranged among the other normal fiber components of the root and the collaterals traveling medially also were scattered throughout the DVN and MVN. From this level caudward, it was impossible to determine precise terminations of the vestibular afferents because of the presence of descending cerebellar degeneration into this same area.

(at 49 (Fig. 20). It is of interest to note the findings in an animal with a more extensive lesion in the large fiber population. In this animal a small knife was used to make a lesion in the rostral one-third to one-half of the superior vestibular ganglion. The animal demonstrated a marked horizontal-rotatory nystagmus to the left for 3 to 4 days postoperatively. This animal was perfused after 7 days survival time.

(a) *Lesion and peripheral degeneration* A large lesion was found involv-

collaterals could be seen taking off at right angles to these descending root fibers and passing obliquely across the LVN without terminating on any of the large or medium sized cells. These collaterals were directed toward the dorsal half of the MVN and were seen to terminate near cells in that part of the MVN and also around medium sized cells at the medial most region of the LVN.

As the degenerated descending root were followed still more caudally in the descending vestibular root and reached levels of the rostral part of the DVN more collaterals were seen to arise and course in a directly medial direction. Preterminal degeneration was noted around some small and medium sized cells in the DVN but none around the large cells. Most of the collaterals passed through the dorsal acoustic stria and terminated in the ventral portion of the MVN. Here preterminal degeneration was seen in the lateral part of the nucleus.

In more caudal regions of the descending vestibular root the degenerating axons became more diffusely arranged among the other normal fiber components of the root and the collaterals traveling medially also were scattered throughout the DVN and MVN. From this level caudalwards, it was impossible to determine precise terminations of the vestibular afferents because of the presence of descending cerebellar degeneration into this same area.

Cat 49 (Fig 20) It is of interest to note the findings in an animal with a more extensive lesion in the large fiber population. In this animal a small knife was used to make a lesion in the rostral one-third to one-half of the superior vestibular ganglion. The animal demonstrated a marked horizontal-rotatory nystagmus to the left for 3 to 4 days postoperatively. This animal was perfused after 7 days' survival time.

(a) *Lesion and peripheral degeneration* A large lesion was found involving

NO 5

Fig. 22. Drawing of the reconstructed lesion and degeneration pattern in animal 5. The light broken lines represent small-sized degenerating fibers.

ing the rostral half of the superior ganglion. From this lesion, large caliber degenerated, myelinated fibers passed peripherally toward the nerves of the superior and horizontal canals. The large number of degenerated fibers formed two compact bundles of fibers as they coursed peripheral to the lesion in the ganglion. These became surrounded by a ring of normal small sized, myelinated fibers as they formed each ampullary nerve of the superior division.

(b) *Central degeneration* The pattern of the central degeneration from this large lesion was essentially the same as in animal 56. Only the intensity was increased proportionately. All the preterminal degeneration in the SVN was localized in the central portion of the nucleus while the periphery was free of degeneration despite the size of the lesion (Fig. 21). The terminal and preterminal degeneration from the degenerated large-sized fibers, therefore, appeared localized to the large cells in the central part of the SVN. In other areas of the vestibular nuclear complex, the pattern of degeneration remained the same as in animal 56, but intensity of degeneration was increased (Fig. 22).

Cat 5 (Fig. 23) A superficial lesion of the caudal half of the superior division ganglion was attempted in this animal. By involving only the most dorsal cell in this part of the ganglion the lesion avoided including the deeper cells innervating the utricular macula. It was found that such a superficial lesion could best be made by barely touching the tip of a small unipolar electrode to the surface of the ganglion and applying 2 milliamperes for 5 seconds.

Following surgery the animal had a barely perceptible horizontal nystag-

ular root (Fig. 25) terminated by means of collaterals on the rostral division of the interstitial nucleus, and finally bifurcated into ascending and descending branches at a more dorsal and lateral point than the larger fibers described in animals 56 and 40.

The ascending branches of the small degenerating axons abruptly turned dorsalward and coursed as individual fibers, or packets of two to three fibers, in the most peripheral zone of the SVN where small neurons populate the nucleus (Fig. 26). These fibers were also seen to give off fine collaterals extending medially across the SVN. Many of these fine ascending fibers continued on into the cerebellum. However the number doing so was less than that entering the nucleus so that some of these fibers probably terminated in the peripheral zone of the SVN.

As the degenerated descending branches traveled in the dorsolateral part of the descending vestibular root they gave off fine collaterals medially in the regions of the caudal ventral IVN and the rostral DVN much as the heavy fibers did in previous animals. They also appeared to end in similar areas of the DVN and MVN. However the pattern of degeneration was more diffuse around the many smaller neurons in these nuclear groups.

Fig. 27 Drawing of the reconstructed lesion and degeneration pattern in animal 8. The broken lines represent both small and large size degenerating fibers.

B Inferior Division (Posterior semicircular canal)

Because of the smaller size of the ganglion to the posterior canal and because there was no practical way of creating selective lesions of large or small fibers in this nerve even the smallest lesions in this ganglion involved both large and small fibers. The description of this lesion therefore concerns both large and small fiber components to the posterior canal crista.

Cal 8 (Fig 27) In this animal the lesion was produced by application of the unipolar electrode tip onto the very caudal aspect of the vestibular ganglion as it arched over the cochlear nerve trunk. This part of the ganglion is solely concerned with posterior canal innervation and afforded an excellent opportunity of creating a selective posterior canal lesion. A current of 2 milliamps was applied for 3 seconds in this animal. Postoperatively the animal exhibited a mild rotatory nystagmus which lasted 2 to 3 days. A survival period of 11 days was allowed before the animal was sacrificed by perfusion.

(a) *Lesion and peripheral degeneration* The lesion was found to involve the caudal end of the inferior vestibular ganglion (Fig 28 A). Degenerated fibers of various diameters were seen only in the posterior canal nerve (Fig 28 B). Degenerated axon could be followed proximally from the lesion coursing toward the rostral half of the vestibular trunk.

(b) *Central degeneration* The degenerated axons were seen to occupy a narrow zone stretching the medio-lateral width of the vestibular root just rostral to the olivocochlear bundle (Fig. 29). These fibers gave off short collaterals, terminating in the caudal division of the interstitial nucleus of the vestibular root (Fig. 30). The incoming axons continued on over the

Fig. 26. Transverse section through the SVN of animal 8 demonstrating the location of ascending branches of degenerating small fibers in the lateral aspect of the nucleus. Compare with Fig. 16 and 21. Broken line delimit the SVN.

ular root (Fig. 25) terminated by means of collaterals on the rostral division of the interstitial nucleus, and finally bifurcated into ascending and descending branches at a more dorsal and lateral point than the larger fibers described in animals 46 and 49.

The ascending branches of the small degenerating axons abruptly turned dorsalward and coursed as individual fibers, or packets of two to three fibers, in the most peripheral zone of the SVN where small neurons populate the nucleus (Fig. 26). These fibers were also seen to give off fine collaterals extending medially across the SVN. Many of these fine ascending fibers continued on into the cerebellum. However, the number doing so was less than that entering the nucleus so that some of these fibers probably terminated in the peripheral zone of the SVN.

As the degenerated descending branches traveled in the dorsolateral part of the descending vestibular root they gave off fine collaterals medially in the regions of the caudal ventral LVN and the rostral DVN much as the heavy fibers did in previous animals. They also appeared to end in similar areas of the DVN and MVN. However, the pattern of degeneration was more diffuse around the many smaller neurons in these nuclear groups.

Fig. 27 Drawing of the reconstructed lesion and degeneration pattern in animal 8. The broken lines represent both small and large size degenerating fibers.

D. Inferior Division (Posterior semicircular canal)

Because of the smaller size of the ganglion to the posterior canal and because there was no practical way of creating selective lesions of large or small fibers in this nerve, even the smallest lesions in this ganglion involved both large and small fibers. The description of this lesion, therefore concerns both large and small fiber components to the posterior canal crista.

Cat 8 (Fig. 27) In this animal the lesion was produced by application of the unipolar electrode tip onto the very caudal aspect of the vestibular ganglion as it arched over the cochlear nerve trunk. This part of the ganglion is solely concerned with posterior canal innervation and afforded an excellent opportunity of creating a selective posterior canal lesion. A current of 2 milliamps was applied for 5 seconds in this animal. Postoperatively the animal exhibited a mild rotatory nystagmus which lasted 2 to 3 days. A survival period of 8 days was allowed before the animal was sacrificed by perfusion.

(a) *Lesion and peripheral degeneration* The lesion was found to involve the caudal end of the inferior vestibular ganglion (Fig. 28 A). Degenerated fibers of various diameters were seen only in the posterior canal nerve (Fig. 28 B). Degenerated axon could be followed proximally from the lesion coursing toward the rostral half of the vestibular trunk.

(b) *Central degeneration* The degenerated axons were seen to occupy a narrow zone stretching the medio-lateral width of the vestibular root just rostral to the olivocochlear bundle (Fig. 29). These fibers gave off short collaterals, terminating in the caudal division of the interstitial nucleus of the vestibular root (Fig. 30). The incoming axons continued on over the

Fig. 26 Transverse section through the VN of animal 15 demonstrating the location of ascending branches of degenerating small fibers in the lateral portion of the nucleus. Compare with Fig. 18 and 21. Broken line delimited the VN.

ular root (Fig. 25) terminated by means of collaterals on the rostral division of the interstitial nucleus, and finally bifurcated into ascending and descending branches at a more dorsal and lateral point than the larger fibers described in animals 56 and 49.

The ascending branches of the small degenerating axons abruptly turned dorsalward and coursed as individual fibers, or packets of two to three fibers, in the most peripheral zone of the VN where small neurons populate the nucleus (Fig. 26). These fibers were also seen to give off fine collaterals extending medially across the VN. Many of these fine ascending fibers continued on into the cerebellum. However, the number doing so was less than that entering the nucleus so that some of these fibers probably terminated in the peripheral zone of the VN.

As the degenerated descending branches traveled in the dorsolateral part of the descending vestibular root, they gave off fine collaterals medially in the regions of the caudal ventral LVN and the rostral DVN much as the heavy fibers did in previous animals. They also appeared to end in similar areas of the DVN and MVN. However, the pattern of degeneration was more diffuse around the many smaller neurons in these nuclear groups.

B. Inferior Division (Posterior semicircular canal)

Because of the smaller size of the ganglion to the posterior canal and because there was no practical way of creating selective lesions of large or small fibers in this nerve, even the smallest lesions in this ganglion involved both large and small fibers. The description of this lesion, therefore, concerns both large and small fiber components to the posterior canal crista.

Cat 8 (Fig. 27) In this animal the lesion was produced by application of the unipolar electrode tip onto the very caudal aspect of the vestibular ganglion as it arched over the cochlear nerve trunk. This part of the ganglion is solely concerned with posterior canal innervation and afforded an excellent opportunity of creating a selective posterior canal lesion. A current of 2 milliamperes was applied for 5 seconds in this animal. Postoperatively the animal exhibited a mild rotatory nystagmus which lasted 2 to 3 days. A survival period of 6 days was allowed before the animal was sacrificed by perfusion.

(a) *Lesion and peripheral degeneration* The lesion was found to involve the caudal end of the inferior vestibular ganglion (Fig. 28A). Degenerated fibers of various diameters were seen only in the posterior canal nerve (Fig. 28B). Degenerated axons could be followed proximally from the lesion coursing toward the rostral half of the vestibular trunk.

(b) *Central degeneration* The degenerated axons were seen to occupy a narrow zone stretching the medio-lateral width of the vestibular root just rostral to the olivocochlear bundle (Fig. 29). These fibers gave off short collateral axons, terminating in the caudal division of the lateral dorsal nucleus of the vestibular root (Fig. 30). The incoming axons continued on over the

dorsal aspect of the descending trigeminal root and actually extended into the lateral portion of the ventral LVN before undergoing the classical bifurcation into ascending and descending rami; this was the most medial bifurcation of any primary vestibular afferent fibers.

These ascending branches turned sharply upward and rostrally traversing the rostral part of the LVN to enter the caudal part of the SVN. In this nucleus these degenerated axons constituted the most medially located fibers passing through the central zone. As they reached the midportion and dorsal half of the nucleus short collaterals were given off which extended medially and ventrally down onto the laminar arrangement of cells in the medial part of the nucleus (Fig 31). The ascending rami then terminated around large cell in the medial part of the central zone of the SVN. It could not be determined with certainty whether some of these degenerating fibers continued on into the cerebellum.

At the very point that the degenerating descending branches could be recognized caudal to the bifurcation of incoming axons, long collaterals

Not the absence of degeneration in the central-lateral and central regions of the nucleus where superior and horizontal canal fibers terminate

were seen travelling obliquely across the ventral LVN to terminate on smaller cells at the medial margin of the LVN and on cells in the dorsal part of the adjacent MVN (Fig. 32)

The degenerating descending rami were well localized at the most medial and dorsal aspect of the descending vestibular root (Fig. 33). As these fibers coursed more caudally collaterals were given off at the level of the rostral DVN. These collateral traveled medially across the DVN at a slightly more dorsal level than those from the superior division lesions although a few preterminal puffs were seen around small and medium cells in this nucleus the large cell were strikingly free of terminals from these collaterals. The collaterals then continued on through the DAS to terminate on cells in the ventral part of the MVN at this level. As more caudal levels of the DVN were reached, the descending branches assumed a more diffuse arrangement in the medial part of the descending vestibular root and gave off scattered collaterals to the DVN and MVN. Again at very caudal levels in these nuclei, descending cerebellar degeneration precluded demonstration of precise termination of vestibular afferents.

Cat JJ (Fig. 34). The lesion in this cat was made by directing a small straight needle vertically down through the caudal part of the superior division ganglion. In this way the cell mass providing small fibers to the superior and horizontal canals as well as the ventral cell mass innervating the utricular macula were involved. Postoperatively no gross nystagmus was noted, while some ataxia was evident. The animal was perfused 6 days after surgery.

(a) *Lesion and peripheral degeneration.* A discrete lesion was found which extended the entire dorsoventral dimension of the caudal one-third of the superior division ganglion (Fig. 35, 1 and 36). Only very small-caliber fibers showing advanced wallerian degeneration were seen peripherally in the superior division. In dorsal section through the superior division the degenerated fibers were arranged as a compact group which were then seen to diverge as the intracapsular nerves were formed. These diverging fibers encircled the normal larger fibers coming from the rostral part of the superior ganglion and were then seen as degenerated fine fibers located in

A. Utricle

Cat 33 (Fig. 24) The lesion in this cat was made by directing a small straight needle vertically down through the caudal part of the superior division ganglion. In this way the cell mass providing small fibers to the superior and horizontal canals as well as the ventral cell mass innervating the utricular macula were involved. Postoperatively no gross nystagmus was noted, while some ataxia was evident. The animal was perfused 6 days after surgery.

(a) *Lesion and peripheral degeneration* A discrete lesion was found which extended the entire dorsoventral dimension of the caudal one-third of the superior division ganglion (Fig. 33-1 and 30). Only very small-caliber fibers showing advanced wall-rim degeneration were seen peripherally in the superior division. In dorsal section through the superior division the degenerated fibers were arranged as a compact group which were then seen to diverge as the two ampullary nerves were formed. These diverging fibers encircled the normal larger fibers coming from the rostral part of the superior ganglion and were then seen as degenerated fine fibers located in

NO 55

Fig 34 Drawing of the reconstructed lesion and degeneration pattern in animal 55. The single heavy broken line represents the degeneration of proximal axons caused by a secondary lesion.

the periphery of each ampullary nerve (Fig 35 B). Degenerated fibers coursing proximally from this part of the lesion occupied the dorsal and caudal part of the rostral half of the vestibular nerve.

Careful reconstruction of the lesion also revealed a minute secondary lesion involving only the central axons of the rostral ganglion cells of the superior division (Fig 36 A). There was no degeneration of these cells or of the large fibers in the ampullary nerves. However a few degenerated large fibers coursed centrally in the rostral part of the vestibular nerve (See Fig 34).

At ventral levels of the superior ganglion were examined many degenerated small fibers were followed out in the utricular nerve toward the macula. At these levels no degenerating fibers were seen in the remainder of the superior division. The degenerated axons coursing proximally from the utricular ganglion were compactly arranged and directed caudo-medially to locate in the ventral part of the caudal division of the vestibular nerve trunk (Fig 36 B).

In the vestibular nerve trunk then two separate bundles of degenerated axons were seen coming from the single lesion in Scarpa's ganglion: the one bundle in the dorsal part of the rostral division was related to the small fiber ganglion population of the canal nerves as was seen in cat 5; the other bundle occupying the rostroventral part of the caudal division represented the degeneration from the injury to the utricular ganglion cells.

(b) *Central degeneration*. Brainstem sections clearly revealed two bundles of degenerating axons in the vestibular root (Fig 37). As the root entered the brainstem the dorsal and rostral group (small canal fibers) occupied the lateral aspect of the root while the ventral-caudal group of fibers became

animals 6 and 56 respectively. A complete description of these groups will therefore not be repeated since their importance here is only to permit distinction between these canal fibers and those from the utricular macula. This animal did demonstrate however the separate localization of the two fiber groups in the SVN and also the importance of careful reconstruction of the lesion and the degenerating fibers peripheral as well as central to this lesion.

The central and caudal group of fibers represented central degeneration from the utricular ganglion lesion. These fibers remained as a compact bundle hugging the lateral aspect of the trigeminal root (Fig. 38A). In this caudal part of the vestibular root, no recognizable part of the interstitial nucleus was seen. However, an occasional solitary large neuron was present. Although the utricular fibers passed immediately adjacent to these neurons no evidence of termination was seen (Fig. 38B).

These degenerating utricular axons bifurcated more laterally than any other vestibular neurons. From reconstruction of serial sections it was seen that the ascending rami curved gradually in a rostral direction to the rostro-

Fig. 37 Transverse section through the brainstem and vestibular root of animal 35. There are two separate bundles (arrows) of degenerating axons in the vestibular root.

animals 5 and 8 respectively. A complete description of these groups will therefore not be repeated since their importance here is only to permit distinction between these canal fibers and those from the utricular macula. This animal did demonstrate however the separate localization of the two fiber groups in the SVN and also the importance of careful reconstruction of the lesion and the degenerating fibers peripheral as well as central to this lesion.

The ventral and caudal group of fibers represented central degeneration from the utricular ganglion lesion. These fibers remained as a compact bundle hugging the lateral aspect of the trigeminal root (Fig. 38A). In this caudal part of the vestibular root, no recognizable part of the interstitial nuclei was seen. However an occasional solitary large neuron was present. Although the utricular fibers passed immediately adjacent to these neurons no evidence of termination was seen (Fig. 38B).

These degenerating utricular axons bifurcated more laterally than any other vestibular neuron. From reconstruction of serial sections it was seen that the ascending, semi-curved gradually in a rostral direction to the rostro-

ventral part of the LVN and traveled directly across this nucleus toward the MVN (Fig. 39). A few of the medium sized neurons in the ventral LVN showed preterminal and terminal degeneration from these degenerated ascending branches (Figs. 40 A-41). The major terminal of these ascending branches, however, appeared to be in the rostral part of the MVN where preterminal degeneration was seen on large and small neurons in the lateral half of the nucleus (Fig. 40 B).

The descending branches were seen as degenerating fibers coursing in the most lateral and ventral part of the descending vestibular root (Fig. 38 B). Collaterals were given off by these descending fibers and filtered through the descending root fibers to enter the rostral DVN where they appeared to contact the same cellular areas as the semicircular fibers. The numerous scattered neurons in the descending vestibular root did not receive any termination from these utricular fibers.

The question of whether these collaterals from the descending utricular branches enter the adjacent MVN was difficult to determine because of the degeneration there from the canal fibers involved in this animal. The amount of terminal degeneration in this part of MVN, however, did not appear to be significantly increased over that seen in cat 5. However, the possibility remains that some utricular axons terminated in this area. Again

During the posterior canal fibers. However, since it was clear from dissected normal specimens that the axons of the saccular nerve form the most caudal fibers of the vestibular nerve trunk, it was possible to separate these caudal bundles and transect them with a small knife. In this way a selective lesion of the saccular axons was created in cat 50. The animal displayed no nystagmus or marked vestibular upset except for that which was associated with cerebellar retraction. The animal was allowed to survive only 4 days before perfusion fixation was performed.

The short survival period of 4 days was allowed because it was found in other cats with saccular lesions that the small saccular fibers displayed

the ganglion and nerve trunk provided a basis upon which to direct the placement of lesions and to reconstruct the degeneration from these lesions.

In the peripheral vestibular branches Sudan Black reliably demonstrated myelin sheaths of extremely fine fibers of one micron or less in diameter. The axis cylinders of these fibers would be difficult to demonstrate consistently with silver techniques that must be applied after lengthy decalcification of the dense petrous bone of the cat. The Sudan Black technique as used in this study can be used to accurately measure these myelin sheath diameters because there is negligible shrinkage when frozen sections are made of these nerves (Gacek & Rasmussen, 1961).

The Van Gieson silver technique as modified by Rasmussen was used to demonstrate the degenerating fibers in the vestibular root and brainstem. As the method is intended to selectively impregnate degenerated fibers, there is always the possibility of nonimpregnation of some abnormal fibers particularly small ones. The excellent report of Eager & Barnett (1966) provided a guideline to reduce this possibility to a minimum.

Evaluation of lesions in Scarpa's ganglion

Three principles were extremely important in the accurate evaluation of lesions in Scarpa's ganglion.

1. The survival time following lesions must assure optimal demonstration of wallerian degeneration in small as well as large fibers in the peripheral vestibular nerve. This period was five to seven days in the cat.
2. The exact extent of the lesion in the ganglion must be carefully reconstructed from serial sections.
3. A comparison must be made between the number of degenerated fibers peripheral and central to the lesion in Scarpa's ganglion.

The importance of these principles is demonstrated by the following.

If a divergent lesion were made in the caudal part of the superior division ganglion deep enough to involve the utricular ganglion cells as well as the dorsal group supplying all fibers to the horizontal and superior canals and a survival time of 12 to 14 days allowed, the resulting degeneration would be extremely difficult to evaluate. After this degeneration period, the extremely fine peripheral processes of the canal ganglion cells would have completely degenerated and product of wallerian degeneration would not be demonstrable while the larger central processes of the same cells and their continuation into the brain stem would be demonstrated. Superficial evaluation of this lesion would lead one to believe that the utricular ganglion project centrally not only to the LVN, DVN and MVN but also to the lateral part of the superior vestibular nucleus—the area to which the small fibers of the superior and horizontal canal project.

However, careful reconstruction of the lesion, and a comparison of the

such advanced degeneration at 6 to 7 days that it was difficult to follow the axonal debris central to their bifurcation in the brainstem.

(a) *Lesion and peripheral degeneration* Since transection of the proximal process (axon) of the saccular ganglion cells was performed in the vestibular nerve trunk, no peripheral degeneration was found in the saccular nerve or any other vestibular branches.

(b) *Central degeneration* The central course of degenerating fibers from this saccular nerve lesion was unique. The degenerating fibers formed the most caudal and dorsal component of the vestibular root. As they proceeded in toward the vestibular nuclei they occupied the most lateral position in this caudal end of the vestibular root (Fig. 43). Some fibers were so far lateral that they cut through part of the restiform body in an almost dorsal direction. Most of the fibers, however, continued along the medial surface of the restiform body until the caudal IVN was reached. Here they bifurcated into very fine ramuli.

The ascending branches continued on in a direct dorsal direction through the part of the LVN adjacent to the restiform body (Fig. 43 and 44A). These did not terminate on IVN cells, but by passed them and ended in the small groups of cells called group "v" by Brodal (Fig. 44B). This group of cells overlays the dorsum of the restiform body and the dorsal IVN. Abundant degeneration was seen in this nucleus. The degenerated saccular axons which coursed through the restiform body appeared to end directly in group "v" without bifurcating.

Very fine descending branches from the incoming saccular fibers were seen to turn ventrally and medially from the point of bifurcation. These fibers appeared to end on a few cells in the most lateral portion of the adjacent LVN and also on the most rostral end of the DVN. At this point it was very difficult to tell where the LVN ended and the DVN began. This degeneration in the IVN and the DVN from the saccular lesion was very modest. Only the projection to group "v" was most impressive in the central degeneration from this saccular nerve lesion.

DISCUSSION

Technique

The success of this study was felt to be largely dependent on a thorough knowledge of the anatomy of the peripheral vestibular nerve and its branches to the vestibular endorgans. This included not only the relationship of the nerve ramuli to different parts of Scarpa's ganglion but also data on the diameters of the nerve fibers making up the vestibular complex. The Sudan Black B method of Rasmussen proved to be a suitable technique.

Familiarity with the vestibular nerve branches was obtained by dissecting a large number of normal ears. Dissection of the branches proximally into

number of degenerating fibers proceeding peripherally from the lesion with the number coursing centrally into the brainstem would alert the observer to the fact that an accurate correlation between endorgan and brainstem cannot be made. Of course a much shorter degeneration period would have obviated much of the difficulty in such a case.

Vestibular efferent fibers involved in lesions of Scarpa's ganglion

The possibility of vestibular efferent fibers interrupted by lesions in Scarpa's ganglion was considered. Lesions involving the caudal part of the superior division ganglion and those involving the ganglion to the posterior canal were the only instances in which this factor need be taken into account. Thorough knowledge of the number, course and distribution of vestibular efferent fibers, at all levels of the vestibular nerve complex (Gacek 1960, 1966, 1967) was most helpful in accurately evaluating such lesions. Discrete lesions were made in the caudal part of the superior division ganglion without involving the main bundles of vestibular efferent fibers (see Fig. 3a, 4). The small degenerating fibers emanating from such a lesion were at least almost entirely afferent dendrites. Furthermore, all efferent fibers would account for only a small fraction of the small sized fibers in the ampullary nerve branches.

Cerebellar degeneration in the evaluation of brainstem projections of vestibular endorgans

As shown in the control group of cats, significant cerebellar cortical degeneration was produced from retraction of the flocculus and adjacent cerebellum. However, for the most part this did not present a problem in the vestibular nuclei. The areas such as the ventral part of the LVN, all except the most rostral and dorsal part of the SVN, all except the caudal half of the MVN and the DVN and the smaller nuclear groups (such as the NV and group 3) were free of such descending cerebellar degeneration even in the severest of the control group.

In the most rostral and dorsal part of the SVN and in the caudal half of the MVN and DVN, diffuse terminal cerebellar degeneration was consistently present and precise statements about the primary vestibular projections to these areas could not be made. Therefore, the caudal regions of the MVN and DVN were left blank in the summary diagrams (Figs. 40, 47) and a question mark was placed over the possible continuation of large semicircular canal fibers from the rostral SVN into the cerebellum. It can be stated, however, that the descending, ramal and collaterals of all endorgans except the saccule, did project caudally beyond the part of the MVN and the DVN shown in the diagram, but that in these areas the termination on cells in the lateral part of the MVN and the medial DVN was very diffuse and became indistinguishable from that of the degenerating cerebellar cortical axons.

Fig. 43. Drawing from dorsal view of the right vestibular nerve and endorgans summarizing the peripheral location of first order neurons. The dark and light areas of the superior division represent the location of large and small caliber neurons respectively of the superior and horizontal canal crista (explained in text this nerve is segmented in the drawing) order to demonstrate the change in position of the large and small fibers in the nerve trunks.

Projection of vestibular endorgans

It was clear that the masses of ganglion cells innervating all three semicircular canal crista converged in the rostral division of the vestibular nerve trunk, while those from the two maculae formed the caudal division (Fig. 43). The compact bundles of efferent fibers of both cochlear and vestibular endorgans were interposed between these two divisions at the ventral aspect of the nerve.

Cristae. While the neurons supplying the posterior canal crista were followed as a distinct bundle from end organ to central termination, it was clearly seen that the two canals of the superior division did not each have an exclusive part of Scarpa's ganglion, nor did they each have a separate central termination. In fact, each of these crista was supplied by nerve fibers from two parts of the ganglion supplying the superior vestibular—a rostral one giving rise to large diameter nerve fibers and a caudal-dorsal one giving rise to small nerve fibers. Even a very small lesion in each of these parts of the ganglion produced approximately equal amount of degeneration in the nerves to each of these two canal crista. In terms of innervation the canal portion of the superior division can be considered as one canal nerve with two separate sensory areas. Phylogenetically this repre-

Fig. 46 Line drawing summarizing the central course and termination of semicircular canal neurons in the vestibular nuclei (See text for explanation of different sized lines)

sented the anterior (superior) of the two vertical canals present in lower vertebrates which in higher vertebrates formed the newer horizontal canal by merely splitting off another sensory area.

Because of the separate ganglionic masses supplying large and small fibers to this canal it was possible to describe its central projection in terms of large and small fibers. Of course the posterior canal neurons also have large and small fiber components, but it was not possible to selectively destroy each of these because of the smaller size of the ganglion to this endorgan. Therefore the posterior canal central projection described concerned both large and small fibers. The diagram (Fig. 46) represents these canal fibers by relative differences in the fibers, i.e., the large and small fibers of the superior division canals are represented by very wide and very thin lines, while the posterior canal projection is represented by a line of intermediate size.

As the canal fibres entered the brainstem in the vestibular root those of the superior division canal were associated with and terminated by means of short collaterals on the cells in the rostral division of the NIV while those of the posterior canal had a similar correlation to the caudal division of the NIV. Only semicircular canal fibers were associated with this classical nucleus and no macular (utricle or saccule) fibers terminated here. A smaller, more peripherally located nucleus, in the vestibular root described by Fuxe (1912) also received semicircular canal fibers collaterals; this nucleus was made of very small cells in contrast to those in the classical NIV. The projection of the NIV is not completely clear although there is some evidence that it like the LVN projects down to the spinal cord (Brudal & Pompeiano 1957). Clearly though it is a nucleus concerned solely with semicircular canal innervation.

The course and termination of the ascending ramus of the posterior canal

and the superior division canal were distinctly different. The posterior canal fibers bifurcated most medially of all the vestibular fibers. As a matter of fact, this bifurcation occurred within the lateral part of the LVN. The ascending branches proceeded through the LVN and entered the central and medial part of the caudal SVN. These fibers then ascended to approximately midway between the dorsal and ventral limits of the SVN and terminated primarily on medium to large cells in the central-medial region and, by way of short collaterals that extended ventromedially onto a lamina of cells reaching the medial limits of the nucleus. The superior division fibers bifurcated more laterally and rostral to the posterior canal fibers, and, accordingly the ascending branches entered and terminated in the central lateral and rostral parts of the SVN. However, these branches gave off long collaterals quickly upon entering the SVN and these collaterals arched medially and dorsally to terminate on the same horizontal lamina of cells in the medial part of the nucleus which received collateral innervation from the posterior canal fibers. In the SVN, then, there appeared to be cell groups which received separately the fibers of the posterior canal and superior division canal and also cells which received collateral innervation from both these canals.

Descending branches from the two canals also were localized separately in the descending vestibular root. Similar collaterals to the other nuclei were formed from the fibers of both canals, but, as a rule, the collateral fibers and innervation of the superior division canal were located just ventral to those of the posterior canal. This held true except for the mid- and caudal regions of the MVN and the DVN where the fibers of all the canals were diffusely mixed.

The termination of the large and small afferent fibers of the superior division canal particularly in the SVN was most interesting. The large fibers traveled up the central part of the SVN and terminated on the larger cell there while the small fibers occupied the small-celled peripheral zone between the center and the restiform body and probably ended on some of these small cells. While it was not possible to determine whether the large fibers proceeded also to a cerebellar termination, it was certain that some of the small fibers did continue on into the cerebellum.

Since morphologically the large fibers appear likely to form the large calyx-like endings on type I hair cells in the cristae while the small ones, along with the small efferent fibers make contact with the phylogenetically older type II hair cell (Wersäll, 1960) there is an indication that the different hair cell types have distinctly different central terminations and, therefore, different functional considerations.

Additional support for such a functional difference between the two types of vestibular hair cell has come from the numerous reports on the ototoxic effect of streptomycin sulfate. It is well known that the streptomycin effect both in human subject (Schuknecht, 1938; Grubb et al., 1962) and in the laboratory animal (Schuknecht, 1938) is measured by the elimination of

Fig 46 Line drawing summarizing the central course and termination of semicircular canal neurons in the vestibular nuclei (See text for explanation of different sized lines)

sented the anterior (superior) of the two vertical canals present in lower vertebrates which in higher vertebrates formed the newer horizontal canal by merely splitting off another sensory area.

Because of the separate ganglionic masses supplying large and small fibers to this canal it was possible to describe its central projection in terms of large and small fibers. Of course the posterior canal neurons also have large and small fiber components, but it was not possible to selectively destroy each of these because of the smaller size of the ganglion to this endorgan. Therefore the posterior canal central projection described concerned both large and small fibers. The diagram (Fig 46) represents these canal fibers by relative differences in the fibers, e.g. the large and small fibers of the superior division canals are represented by very wide and very thin lines, while the posterior canal projection is represented by a line of intermediate size.

As the canal fibers entered the brainstem in the vestibular root those of the superior division canal were associated with and terminated by means of short collaterals on the cells in the rostral division of the NIV, while those of the posterior canal had a similar correlation to the caudal division of the NIV. Only semicircular canal fibers were associated with this classical nucleus and no macular (utricle or saccule) fibers terminated here. A smaller more peripherally located nucleus in the vestibular root described by Iuse (1912) also received semicircular canal fibers collaterally; this nucleus was made of very small cells in contrast to those in the classical NIV. The projection of the NIV is not completely clear although there is some evidence that it like the LVN projects down to the spinal cord (Brodal & Compagno 1957). Clearly though it is a nucleus concerned solely with semicircular canal innervation.

The course and termination of the ascending ramus of the posterior canal

and the superior division canal were distinctly different. The posterior canal fibers bifurcated most medially of all the vestibular fibers. As a matter of fact, this bifurcation occurred within the lateral part of the LVN. The ascending branches proceeded through the LVN and entered the central and medial part of the caudal SVN. These fibers then ascended to approximately midway between the dorsal and ventral limits of the SVN and terminated primarily on medium to large cells in the central medial region and, by way of short collaterals that extended ventromedially onto a lamina of cells reaching the medial limits of the nucleus. The superior division fibers bifurcated more laterally and rostral to the posterior canal fibers, and, accordingly the ascending branches entered and terminated in the central-lateral and rostral parts of the SVN. However these branches gave off long collaterals quickly upon entering the SVN and these collaterals arched medially and dorsally to terminate on the same horizontal lamina of cells in the medial part of the nucleus which received collateral innervation from the posterior canal fibers. In the SVN then, there appeared to be cell groups which received separately the fibers of the posterior canal and superior division canal and also cells which received collateral innervation from both these canals.

Descending branches from the two canals also were localized separately in the descending vestibular root. Similar collaterals to the other nuclei were formed from the fibers of both canals, but, as a rule the collateral fibers and innervation of the superior division canal were located just ventral to those of the posterior canal. This held true except for the mid and caudal region of the SVN and the DVN where the fibers of all the canals were diffusely mixed.

The termination of the large and small afferent fibers of the superior division canal, particularly in the SVN was most interesting. The large fibers traveled up the central part of the SVN and terminated on the larger cell there while the small fibers occupied the small-celled peripheral zone between the center and the restiform body and probably ended on some of these small cells. While it was not possible to determine whether the large fibers proceeded to a cerebellar termination it was certain that some of the fine fibers did continue on into the cerebellum.

Since morphologically the large fibers appear likely to form the large calyx like ending on type I hair cells in the cristae while the small ones, along with the small efferent fibers make contact with the phylogenetically older type II hair cell (Wersäll 1960) there is an indication that the different hair cell types have distinctly different central terminations and, therefore different functional considerations.

Additional support for such a functional difference between the two types of vestibular hair cell has come from the numerous reports on the ototoxic effect of streptomycin sulfate. It is well known that the streptomycin effect is the same in the guinea pig (Schuknecht, 1958; Crayth et al 1965) and in the laboratory animal (Schuknecht, 1958) is measured by the elimination of

Fig 47 Lin drawing summarizing the central course and termination of neurons supplying the otolith end organs.

ocular response to semicircular canal stimulation whether it be thermal (caloric) or rotational (post rotational). At this endpoint histological examination has demonstrated a significant number of remaining hair cells in the cristae. It has also been shown by electromicroscopy that streptomycin affects type I hair cells before type II cells (Wersäll & Hawkins, 1969; Spoendlin 1968).

Vacuolae The vestibular neurons from the utricular and saccular maculae comprised the caudal part of the incoming vestibular root. In so doing they showed striking differences from canal fibers with regard to termination (Fig 47). The macular fibers did not have terminals on the interstitial nucleus of the vestibular root (nor on similarly located neurons in the root) and they did not send ascending branches up to the SVN. The utricular afferents did terminate on cells in the ventral LVN.

The neurons of the utricular nerve appeared to be mainly small fibers with a smaller number of large fibers scattered evenly throughout. The ascending rami of the utricular neurons passed through the rostro-ventral portion of the LVN. In doing so they terminated on a surprisingly small number of medium to large neurons in this nucleus. The main destination of these ascending rami appeared to be the rostral part (adjacent to the LVN) of the MVN. The influence of the utricular macula on upper spinal cord muscle reflexes (by way of the rostro-ventral LVN) and the mediation through the MVN of compensatory eye movements from utricular stimulation may be emphasized by these connections. The descending branches of the utricular neurons appeared to converge in the rostral medial part of the DVN in the same area as the descending branches from canal fibers. This appeared to be an area where all the vestibular endorgans (and cerebellum) converged on a relatively limited area in the vestibular nuclear complex and perhaps on the same neurons.

The saccular projection was the most unique of the vestibular endorgans. Analysis of the saccular nerve revealed that it is comprised predominantly of small fibers with fewer large fibers being present moreover numerically it was the smallest of the vestibular branches (Gacek & Rasmussen 1961). The saccular fibers were the most dorsal and caudal of all vestibular root fibers. Although the short descending branches converged on the rostral DVN area and a very small part of the ventral LVN the outstanding projection was that of the ascending branches. These terminated in the small group of cells called group "v" by Brodal. This cell group was described previously by others (Fuse 1912) and does not appear to belong to the classical cerebellar or vestibular nuclei.

Indications are from the long controversy over the function of the sacculus and from the fact that a definite function has never been clearly demonstrated, that the sacculus is a special case in the physiology of vestibular endorgans. Anatomical support for this is provided by this unique projection to the group "v" nucleus.

Value of physiological study of vestibular labyrinth

As stated in the introduction of this report, this study was undertaken to provide anatomical data of use to the neuro-physiologist. Most experiments on the function of different vestibular endorgans have involved the opening of the labyrinth itself which introduces an unknown but significant factor in all endorgans. With the operative approach and anatomical data presented in this study it is hoped that the proper physiological study can be designed and carried out to elucidate the function and basic neuro-physiology of not only the specific vestibular endorgans but hopefully different functional units within an endorgan.

SUMMARY

The course and central termination of first order bipolar neurons from the vestibular sense organs was determined in the cat. Wallerian degeneration of the central and peripheral axon of cell bodies injured by small lesion in Scarpa ganglion was demonstrated by the Santa Aliver and the Sudan Black B techniques. Reconstruction of the lesions and degeneration patterns of forty-seven animals revealed the following:

1. Regardless of the peripheral location of the semicircular canal ampullar (the central processes of all neurons supplying the cristae comprised the rostral two-third of the vestibular nerve and root the neurons innervating the maculae made up the remaining caudal portion of the nerve.
2. Neuron from the cristae terminated by means of short collaterals in the terminal nucleus of the vestibular root, then proceeded into the brainstem.

Fig 47 Lin drawing summarizing the central course and termination of neurons supplying the otolith end organ

ocular response to semicircular canal stimulation whether it be thermal (caloric) or rotational (post rotational). At this endpoint histological examination has demonstrated a significant number of remaining hair cells in the crista. It has also been shown by electronmicroscopy that streptomycin affects type I hair cells before type II cells (Wersall & Hawkins 1962, Spoendlin 1966).

Maculae The vestibular neurons from the utricular and saccular maculae comprised the caudal part of the incoming vestibular root. In so doing they showed striking differences from canal fibers with regard to termination (Fig 41). The macular fibers did not have terminals on the interstitial nucleus of the vestibular root (nor on similarly located neurons in the root) and they did not send ascending branches up to the SVN. The utricular afferents did terminate on cells in the ventral LVN.

The neurons of the utricular nerve appeared to be mainly small fibers with a smaller number of large fibers scattered evenly throughout. The ascending ramuli of the utricular neurons passed through the rostro-ventral portion of the LVN. In doing so they terminated on a surprisingly small number of medium to large neurons in this nucleus. The main destination of these ascending ramuli appeared to be the rostral part (adjacent to the LVN) of the MVN. The influence of the utricular macula on upper spinal cord muscle reflexes (by way of the rostro-ventral LVN) and the mediation through the MVN of compensatory eye movements from utricular stimulation may be emphasized by these connections. The descending branches of the utricular neurons appeared to converge in the rostral medial part of the DVN in the same area as the descending branches from canal fibers. This appeared to be an area where all the vestibular endorgans (and cerebellum) converged on a relatively limited area in the vestibular nuclear complex and perhaps on the same neurons.

where each axon bifurcated into an ascending and a descending branch. The ascending branches terminated in the superior vestibular nucleus and the cerebellum while the descending branches travelled in the vestibular root and gave off collaterals passing medially into the lateral medial and descending vestibular nuclei.

A separate central localization was found for neurons supplying the posterior canal crista as opposed to those supplying the cristae of the superior vestibular division canals (superior and horizontal). This was particularly evident in the interstitial nucleus of the vestibular root, the superior vestibular nucleus and the descending vestibular root and nucleus.

3. Neurons from the maculae did not terminate in the interstitial nucleus of the vestibular root or the superior vestibular nucleus. The ascending branches of the utricular neurons terminated in the rostral-ventral lateral vestibular nucleus and the rostral medial vestibular nucleus, while the descending branches gave off collaterals to the caudal medial vestibular nucleus and rostral descending vestibular nucleus. The central termination of saccular neurons was located mainly in the group γ nucleus (Brodal) and to a lesser extent in the lateral and descending vestibular nuclei.

4. In the superior vestibular nucleus the large caliber neurons from the superior division cristae terminated around the large cells in the center of the nucleus while the small diameter neurons from these endorgans ended peripherally in the nucleus where small cells predominate. Such findings indicate different functional properties for the type I and type II vestibular hair cells. Large and small diameter nerve fibers were also found in all the vestibular nerve branches.

These anatomical data are presented to aid physiological study of the vestibular labyrinth and the first order neuron.

1 INTRODUCTION

In the year 1899 Siebenmann spoke of "parallel features" as the result of his examination of hearing function: one part corresponded to the stapedia ankylosis while the other presented an atypical picture in the form of a progressive nerve deafness. According to Siebenmann this duality was previously observed by Troeltsch (1858) but as the latter did not have any knowledge about otosclerosis, it is Siebenmann who designed "labyrinthine otosclerosis" as a clinical entity. Some of the terms applied later to the condition have been: active capsular otosclerosis, cochlear type retrofenestral otosclerosis and perceptible hearing loss without stapedia ankylosis.

Krepuska and Krepuska (1936) pointed out that deafness can be the result of osseous changes in the cochlear capsule without stapedia ankylosis but it is not possible to separate labyrinthine deafness of this kind from others of inner ear origin without histologic evidence. Sixty years after Siebenmann's first description, Shambaugh (1959) still wrote that, other than microscopic examination of the temporal bone there was no reliable method for diagnosing "pure labyrinth affection". Seven years later Huxley (1966) felt that cochlear otosclerosis might be the greatest single cause of nerve deafness. Lack of histologic material may lead to different opinions. Rosair (1960) considered otosclerosis of the inner ear as uncommon.

Very many tabulles will be quoted. Fletcher (1962) studied the collection of Lange among about 1500 histological series of temporal bones he found 93 with otosclerosis, localized in 27 cases around the round window probably in hearing contact between the cochlear capsule and the otosclerotic focus. The material of Cujid (1944) revealed 49 patients with histologic otosclerosis: contact between cochlear capsule and otosclerotic focus occurred in 1. He declared that foci in independent areas in superior anterior or inferior part of the cochlear capsule rarely grow to a size large enough to affect the hearing. Such anatomic discrepancy with our findings is one of the evidences of different material, selected on basis of surgical indications or not selected at all. Whether tabulated as one or the other it is obvious that cochlear involvement is far from being a rarity. Nylén (1949) was one among others, to emphasize the frequency of invasion of the capsule of the labyrinth.

Further discussion of otosclerosis within the otic capsule is extant in our collection will be discussed later in this paper.

1 INTRODUCTION

In the year 1893 Siebenmann spoke of "parallel features" as the result of his examination of hearing function: one part corresponded to the stapedial ankylosis while the other presented an atypical picture in the form of a progressive nerve deafness. According to Siebenmann this duality was previously observed by Troeltsch (1858) but as the latter did not have any knowledge about otosclerosis, it is Siebenmann who designed "labyrinthine otosclerosis" as a clinical entity. Some of the terms applied later to the condition have been: active capsular otosclerosis, cochlear type, retrofenestral otosclerosis and perceptible hearing loss without stapedial ankylosis.

Krepuska and Krepuska (1936) pointed out that deafness can be the result of various changes in the cochlear capsule without stapedial ankylosis but it is not possible to separate labyrinthine deafness of this kind from others of inner ear origin without histologic evidence. Sixty years after Siebenmann's first description, Shambaugh (1959) still wrote that, other than microscopic examination of the temporal bone there was no reliable method for diagnosing "pure" labyrinth affection. Seven years later Hoople (1966) felt that cochlear otosclerosis might be the greatest single cause of nerve deafness. Lack of histological material may lead to different opinions. Roussier (1960) considered otosclerosis of the inner ear as uncommon.

Few of many statistics will be quoted. Fletscher (1932) studied the collection of Lange among about 1500 histological series of temporal bones. He found 99 with foci of ossification, localized in 27 cases around the round window probably indicating contact between the cochlear capsule and the otosclerotic focus. The material of Guild (1944) revealed 49 patients with histologic evidence of contact between cochlear capsule and otosclerotic focus occurred in 11. He declared that foci in independent areas in superior, anterior or inferior part of the cochlear capsule rarely grow to a size large enough to affect the hearing. Such anatomic discrepancy with our findings is one of the evidences of different material selected on basis of surgical indications or not selected at all. Whether tabulated or not, one or the other, it is obvious that cochlear involvement is far from being a rarity. Nylen (1949) was one among others, to emphasize the frequency of invasion of the capsule of the labyrinth.

Further discussion of otosclerosis within the otic capsule as extant in our collection will be discussed later in this paper.

2 MATERIAL AND METHODS

At the present time there are 50 documented cases in our series. In three instances otosclerosis is unilateral. Besides this material now processed in sectional series, another group of about the same number is, at the present time in different stages of histological processing. There were 24 males and 26 females. Ages varied between 45 and 83 years.

All represent "surgical" cases either operated or the opposite unoperated side or destined for operation which for some reason was not performed. Consequently the material is of a very special nature comprising only instances where the disease caused severe enough hearing loss for which the patient sought help.

Statistical evaluation has not been attempted for two reasons: (1) the group of temporal bones was not characteristic for otosclerosis in general; (2) the number of processed cases is continuously increasing and the tabulation would have to be repeatedly changed by addition of new data. No attempt is made to compare our figures statistically with data originating from other sources.

Because this study is looking for the anatomical basis of hearing loss due to otosclerosis attention has centered on those cases showing contact between the cochlear capsule and otosclerotic focus. Among the 50 cases, 21 showed bilateral and 16 unilateral contact. This amounts to 86 percent, certainly a somewhat unexpectedly high proportion explained by the method of obtaining temporal bones by the Los Angeles Foundation of Otology: the specimens have come from individuals with a progressive affliction.

According to the special aims of this study changes around the stapedial footplate were not considered except as part of the analysis of the cochlear labyrinthine change.

A number of otosclerotic temporal bones outside this series served as an addition to the evaluation. However they are not described and are not illustrated in this study. There were a number of points of interest in this group that have been used for comparison. Obviously not all the questions of relevance could be discussed.

Technically the use of wire prostheses created a particular problem in temporal bone processing. The difficulty was circumvented by determining by X-ray the exact position of the wire within the temporal bone which was then sectioned in a plane dictated by the orientation of the embedded prosthesis. When the wire was reached, the celloidin block was inverted and sectioned starting from the bottom. Thus comparatively few sections

are lost. The slice containing the wire can then be studied as an entity including photography.

A factor of primary importance is preservation of the temporal bone which may have been obtained after several days of delay. Early embalming at the mortuary is a distinct help in preserving soft tissues.

Experience has shown that the sensory structures, especially the organ of Corti, do not show a stage of preservation parallel with the condition of the entire body. A cadaver in state of high decay may contain an intact Corti organ; on the other hand, bodies obtained under comparatively favorable conditions may present a flat row of cells.

Lately decalcification by acid has been replaced by the versene technique as adapted for the temporal bone by Gussen and Donahue (1963). By this method the often vexing problem of overdecalcification can be safely avoided.

The relative condition of the single elements within the temporal bone should command selective evaluation of the findings in the different tissues. The accuracy with which the delicate sensory organs, seen under the microscope can be evaluated has been doubted by some since the beginning of histological examination. This was re-emphasized as late as 1968 by Altman, who warned that histological methods presently available for human temporal bones are often inadequate to establish beyond a doubt their intralabyrinthine boundaries. Confidence in the perfection of an individual's own preparation has been the origin of more than one assumption, or even general theory regarding function of the normal and the pathological cochlea and vestibulum.

Involvement of the carotid canal (Fig. 3) was infrequent. It took the form of a more or less wide protrusion replacing the wall for a generally short stretch. Significant deformation of the canal did not occur. In one case a large fibrous resorptive island within the focus opened directly into the canal.

Penetration of parts of the capsular wall of the vestibulum did not change the configuration of the saccular or the utricular maculae (Figs. 4, 5). Cristae including cupulae showed their well known resistance compared to the condition of the organ of Corti.

A fault in the semicircular canals was not frequently seen. The section of the horizontal canal was partly (Fig. 6) or completely transformed. Once the entire circumference was formed by otosclerotic bone, this case was one of the very few where the involvement reached the tegmen over the labyrinth, under an unharmed dura. Some examples show complete encroachment of the lumen of the horizontal canal at the site of a fenestration operation. The mechanism of penetration at the canal wall is identical with that to be described in detail for the cochlear capsule: the metaplastic process advances to the lumen with a resulting contour deformity. Typical resorptive formation (see below) is seen, the fragmented particles taking the shape of vacuoles in a continuous row.

3 HISTOPATHOLOGICAL FINDINGS

Involvement of the *middle ear* occurred in the form of a deeper protrusion of the promontory (Fig. 1) and a narrowing of the tympanic lumen. Where otosclerotic bone reached the lumen of the middle ear the wall lost its smoothness, but the "rosary" caused by fragmentation (see below) was absent, as there is no endosteal layer at this side. Only a slight degree of engorgement was present in the covering mucosa. Schwarz's sign could hardly be observed in these cases. In a temporal bone showing otosclerosis elsewhere a multilocular cyst protruded from the epitympanum while smaller exostoses formed under the tympanic mucous membrane.

No instances were observed where the tissue of the *large ossicles* underwent otosclerotic changes. Their normal, endless variance as to structure was present without any characteristic metaplasia.

Two nervous structures bounded by the middle and the inner ear respectively are the nerve of Jacobson and the facial.

Instances of involvement of the *nerve of Jacobson* showed the canal, partly without compression of the nerve itself. Fig. 2 shows the opening on the tympanic surface uninvolved. In other specimens the lamellae of the cortical bone succumbed to the attack. Another variant showed the roof of the canal transformed with part of the bottom free, albeit finger-like protrusions testified to the approach of complete inclusion.

Replacement of the wall of the *facial canal* was the object of a separate study (Kelemen and Linthicum, 1963).

The otosclerotic focus advances by sheer physical force. At the inner surface of the bony capsule this shows in the form of cracks. The endosteum is burst open by the mass coming from the periphery (Fig. 3). The endosteum may remain intact but a crack appears in the endosteal bony layer indicating the approaching focus. These fissures are not to be confused with the crack around the otosclerotic focus which delimits it from the original capsular bone. This is caused by different contraction coefficients in the fixation fluid, due to the different chemical composition of the two kinds of bone.

The pressure will manifest itself as originating with finger-like processes protruding from the main mass of the focus, singly or in groups (Fig. 4). The contour of the still intact capsular bone may be seen bulging before the pressure of the approaching focus. A protruding otosclerotic finger may precede bulkier parts of the focus, albeit the latter has already partially replaced the endosteum and has initiated destruction. On one occasion a proliferating finger was seen advancing parallel to the capsular wall.

Considering the localization of the always sharp boundary between the

No case was observed with involvement of the immediate surroundings of the *vestibular aqueduct*. Several cases showed the *congenital fissure* in its most typical location connecting the niche of the round window with the base of the posterior crista (Fig 7)

The primary concern of this investigation was the involvement of the *cochlear capsule* by otosclerosis. Conversion of the capsular bone to otosclerosis has been studied in detail particularly as it relates to functional changes that might occur when the suspension mechanism of the basilar ligament is distorted

Because of our special interest the delicate structure of the tissue of the spiral ligament created a very involved problem

In the illustrations, the stain applied when not noted otherwise was hematoxylin-eosin

The histological work was done by Mrs Agnes Cherehian Ward H T (ASCP) and Mrs Ruth Gregory Creulach the microphotography by Mr Lloyd Matlovsky. (Regarding processing of temporal bones α Cherehian Ward, 1967)

Replacement of the endosteum is the last step in the progress of the focus against the cochlear lumen (Fig. 28). This process follows an essentially regular course. But it must be emphasized that pressure exerted by the advancing new bone established within the external layers of the capsule before the endosteum is reached may already manifest itself within the latter by the appearance of cracks (Fig. 29).

The most conspicuous phenomenon of replacement is a sequence which may be called *fragmentation*. The endosteal layer is broken up into small particles (Fig. 30) and the latter form a *rosary* (row of beads) before disappearing definitely under the advancing otosclerotic mass. The particles may assume the form of vacuoles (Fig. 31). The same may be observed where the otosclerotic mass surrounds a semicircular canal (Fig. 32). Some times it is hard to decide whether this margin belongs to the transformed endosteal layer or to the invading bone. In the latter case the much wider meshes of the otosclerotic bone must have changed into smaller and remarkably uniform vacuoles. So interpreted, the rosary represents the initial form of resorption of the endosteal layer before definite replacement.

Fragmentation accomplished, the original smoothness of the caseous contour is definitely lost (Fig. 33). The particles of this mosaic layer remain until their disappearance at the area of contact with the terminal layers of the fibers of the spiral ligament (Fig. 34). When this phase ends, attachment of the spiral ligament to the concavity of the capsular wall will never be reestablished in its original firmness.

The periosteum (endosteum) may line, unbroken, the original bone as well as the transformed section. Or it may be destroyed providing access for the direct contact of the otosclerotic bone with the lumen of the scalae. Isolated fibers of the disintegrating periosteum produce a frayed border (Figs. 34-35-36).

This transformation of the attachment of the spiral ligament, and with it of the basilar membrane into otosclerotic bone is of prime importance. The three layers of the ligament as detailed by Neubert (1930 see below) remain recognizable but frequently with garbled boundaries, as the layers are permeated by cysts. Regarding the latter it is not certain whether they represent artifacts in this conglomerate of loose fibers which may change their position during fixation, similar to that which happens to Retzius's membrane.

In many cases, the dense external layer of the ligament was well represented, but compressed by the advancing new bone. This resulted in considerable deformation of the capsular contour. Edematous inhibition, a result of vascular damage by the otosclerotic penetration, produced a more even picture of the spiral ligament after obliteration of the normal differentiation of its layers. By this mechanism larger cysts are created. Instructive pictures appear where the dense external layer of the ligament, hardly distinguishable from the periosteum, meets the fragmented endosteal bone. The fibers of the ligament still penetrate the broken-up bone adjacent to it.

original bone and the focus progressing toward the cochlear lumen one has to distinguish between comparatively mute areas, lying outside the area of attachment of the spiral ligament and functionally significant ones covering partially or totally the area behind the latter

Contour changes within the cochlea varied markedly from mild flattening of the concave walls to gross alteration with narrowing of the lumen and the occurrence of protuberances in form of exostoses. The concave contour may assume an angulated shape. Angulations may become critical when developed behind the anchorage of the basilar membrane (Fig 10). A high degree of deformity transformed the scala tympani into a funnel shaped space (Fig 11). In some instances the entire wall seemed to advance while nearby the protrusion assumes the character of an exostosis (Figs 12, 13, 14).

In two cases, in contact with the otosclerotic focus, non-otosclerotic bone filled the tympanic scala of the basal turn (Figs 15, 16, 17, 18). In another case of labyrinthine invasion by otosclerosis, non-otosclerotic bone filled the perilymphatic space of the horizontal canal (Fig 19).

The cochlear contours can be altered on occasions by penetration of otosclerotic bone into *interasalar septa* with resultant endosteal destruction (Fig 20). Progression through the interasalar septum may reach the modiolus.

In the region of the *round window* the membrane can be involved in several ways. The shape of the annulus may be altered (Fig 21) at the cochlear aspect of the membrane. A lamina of otosclerotic bone can form a duplication (Fig 22). The window may be bridged over by a mass which totally buries the membrane and protrudes into the niche transforming the latter into a narrow cavity (Fig 23).

The cochlear orifice of the *cochlear aqueduct* was found in some instances completely surrounded by otosclerotic bone which accompanied the duct along a portion of its course. No complete closure was observed. One case (with a dilated cochlear orifice) without otosclerotic bone in the immediate vicinity but present elsewhere in the cochlear capsule showed the endothelial membrane continuing unbroken over the orifice as described by Wallner (1947).

The newly established otosclerotic wall of the scalae may respect the original contour but rather than smooth is wavy in a high or moderate degree (Figs 24, 25). *Resorption cavities* inside the focus are by a fibrous network frequently reach the inner surface either in a silent "mute" region or over the spiral ligament (Fig 26). An entire system of similar spaces may form in series (Fig 27).

Evaluation of the mechanism by which spongiotic or sclerotic bone reached the cochlear capsule did not give any clear-cut results, but certainly is worth further investigation. Either one or the other kind of metaplastic bone advanced against the capsule or both participated in the attack.

Otosclerotic foci of the so-called "burnt out" character are extant in our collection, but no example presented itself within the series here discussed.

Replacement of the endosteum is the last step in the progress of the focus against the cochlear lumen (Fig. 28). This process follows an essentially regular course. But it must be emphasized that pressure exerted by the advancing new bone established within the external layers of the capsule before the endosteum is reached may already manifest itself within the latter by the appearance of cracks (Fig. 29).

The most conspicuous phenomenon of replacement is a sequence which may be called *fragmentation*. The endosteal layer is broken up into small particles (Fig. 30) and the latter form a rosary (row of beads) before disappearing definitely under the advancing otosclerotic mass. The particles may assume the form of vacuoles (Fig. 31). The same may be observed where the otosclerotic mass surrounds a semicircular canal (Fig. 32). Sometimes it is hard to decide whether this margin belongs to the transformed endosteal layer or to the invading bone. In the latter case, the much wider meshes of the otosclerotic bone must have changed into smaller and remarkably uniform vacuoles. So interpreted, the rosary represents the initial form of resorption of the endosteal layer before definite replacement.

Fragmentation accomplished, the original smoothness of the osseous contour is definitely lost (Fig. 33). The particles of this mosaic layer remain until their disappearance at the area of contact with the terminal layers of the fibers of the spiral ligament (Fig. 34). When this phase ends, attachment of the spiral ligament to the concavity of the capsular wall will never be reestablished in its original firmness.

The periosteum (endosteum) may line unbroken, the original bone as well as the transformed section. Or it may be destroyed providing access for the direct contact of the otosclerotic bone with the lamina of the scalae. Isolated fibers of the disintegrating periosteum produce a frayed border (Figs. 34-35-36).

This transformation of the attachment of the spiral ligament, and with it of the basilar membrane into otosclerotic bone is of prime importance. The three layers of the ligament as detailed by Neubert (1930 see below) remain recognizable but frequently with garbled boundaries, as the layers are permeated by cysts. Regarding the latter it is not certain whether they represent artifacts in this conglomerate of loose fibers which may change their position during fixation, similar to that which happens to Reissner's membrane.

In many cases, the dense external layer of the ligament was well represented, but compressed by the advancing new bone. This resulted in considerable deformation of the capsular contour. Edematous inhibition, a result of vascular damage by the otosclerotic penetration, produced a more even picture of the spiral ligament after obliteration of the normal differentiation of its layers. By this mechanism larger cysts are created. Instructive pictures appear where the dense external layer of the ligament, hardly distinguishable from the periosteum, meets the fragmented endosteal bone. The fibers of the ligament still penetrate the broken-up bone adjacent to it.

Figs. 31 and 32 (A, B, C, D) Examples of malalignment of the cochlea plate by the otosclerotic process.

In some cases there is a separation of the two (as e.g. Fig. 37). Warping of the basilar membrane as it enters the apex of the spiral ligament depends too much on the hazards of the histological processing to represent conditions in vivo.

34

The same skepticism must prevail regarding the organ of Corti. While in many instances its good preservation represents *in vivo* conditions, the rate of disintegration does not give reliable information regarding the status before death, i.e. damage done by post mortem changes.

Otosclerosis destruction involving the internal auditory canal can be divided into three distinct steps (1) Metaplasia reaches the walls of the

canal (2) New bone protrudes into the lumen of the canal (3) The 8th nerve is directly attacked by otosclerotic excrescences

1 The canal wall can show considerable masses of the new bone but, besides the breaking up of the originally smooth contour the lumen is fully conserved (Figs. 38-39) This form is infrequent as the focus generally penetrates deeper and causes more disorder

2 The new bone surrounds the canal narrowing it in a very irregular way (Figs. 40-41-42) Into the center of a large resorption island, in a focus around the inner meatus, a spiny exostosis has grown (Fig. 43) In other cases of otosclerosis, a non-otosclerotic exostosis grew into the inner meatus (Fig. 44) Over the focus located in the wall of the inner meatus, the thickened dura was engorged Schwartz's phenomenon in this location

3 Direct attack against the 8th nerve took different forms Buckling inward of the newly formed mass caused deviation and stretching of the fibers (Fig. 45) Sharper protrusions caused a more conspicuous band in the nerve (Fig. 46) Finally spine-like protrusions penetrated the trunk (Fig. 47)

Potential danger to nerves by sharp bony spurs at their divisions (facial and chorda cochlear and vestibular branches of the 8th nerve in the inner meatus) was pointed out previously (Kelemen 1934)

No causal connection can be constructed between otosclerosis and *psammomas* in the dura of the inner meatus. However they were seen so often and so conspicuously distributed in intimate relation to otosclerotic foci that they should be mentioned here Long rows lined the walls in vicinity of the focus (Fig. 48) They showed a predilection to nestle in the anfractuosités of a focus (Figs. 49-50) Some parallelism can be constructed for this predilectional location by their vascular origin and the above-mentioned engorgement over the otosclerotic focus. One giant specimen showed besides a lamellary cortex a small vessel in its center and even osteoblast-like cortical seams (Fig. 51) Here possibly not a single vessel but a small vascular conglomerate underwent the calcifying process.

Figs. 53 (A B C D) and 45 (1 B C D) represent examples of maximal involvement of the cochlear capsule by the otosclerotic process.

Evaluation of several instances with non-otosclerotic lamellar bone filling the scala tympani in contact with the otosclerotic focus shall wait until more cases with comparable cases are obtained

4 AUDIOMETRIC CONSIDERATIONS

Several reports indicated in past years that there is no relationship between otosclerosis and sensori neural hearing loss (Gullid, 1933; Feldman, 1950; Glorig and Gallo, 1962). However many clinicians with a large number of otosclerotic patients are convinced that a relationship does exist (Cart, 1962, 1963; Shambaugh, 1964; Derlacki and Valvassori, 1965; House, 1966).

Continuing correlation of audiometric tests with histopathologic findings tends to indicate at the present time, that there exists a definite relationship.

TABLE 1 Age distribution of individuals with otosclerosis in the entire collection

	Range	Average
Without cochlear involvement	47-80	66
With cochlear involvement	45-83	63

TABLE 2 A Composite audiogram of the individuals in whom the lesion was limited to the footplate and vestibule

The asterisk (*) indicates the average bone conduction level of this group. The upper dotted line represents the BC level of the individual with the best threshold and the lower dotted line indicates the threshold of the patient with the poorest hearing. The individual with this group showed complete loss of bone conduction.

TABLE 2 B Composite audiogram of the individuals in whom the otosclerotic lesion invaded the endosteal layer of the cochlear capsule

The solid line represents the average bone conduction threshold in this group. The upper dotted line represents the threshold of the patient with the best BC level. The arrows indicate that several patients had no measurable bone conduction. (BC thresholds converted to ISO standards.)

canal (2) New bone protrudes into the lumen of the canal (3) The 8th nerve is directly attacked by otosclerotic excrescences

1 The canal wall can show considerable masses of the new bone but besides the breaking up of the originally smooth contour the lumen is fully conserved (Figs 38-39) This form is infrequent as the focus generally penetrates deeper and causes more disorder

2 The new bone surrounds the canal narrowing it in a very irregular way (Figs 40-42) Into the center of a large resorption island in a focus around the inner meatus, a spiny exostosis has grown (Fig 43) In other cases of otosclerosis, a non-otosclerotic exostosis grew into the inner meatus (Fig 44) Over the focus located in the wall of the inner meatus, the thickened dura was engorged Schwartz's phenomenon in this location

3 Direct attack against the 8th nerve took different forms. Buckling in ward of the newly formed mass caused deviation and stretching of the fibers (Fig 45) Sharper protrusions caused a more conspicuous bend in the nerve (Fig 46) Finally spine-like protrusions penetrated the trunk (Fig 47)

Potential danger to nerves by sharp bony spurs at their divisions (facial and chorda cochlear and vestibular branches of the 8th nerve in the inner meatus) was pointed out previously (Kelemen 1974)

No causal connection can be constructed between otosclerosis and *psammomas* in the dura of the inner meatus. However they were seen so often, and so conspicuously distributed in intimate relation to otosclerotic foci, that they should be mentioned here. Long rows lined the walls in vicinity of the focus (Fig 48) They showed a predilection to nestle in the anfractuosités of a focus (Figs. 49-50) Some parallelism can be constructed for this predilectional location by their vascular origin and the above-mentioned engorgement over the otosclerotic focus. One giant specimen showed besides a lamellary cortex a small vessel in its center and even osteoblast like cortical seams (Fig 51) Here possibly not a single vessel but a small vascular conglomerate underwent the calcifying process.

Figs 53 (A B C D) and 44 (A B C D) represent examples of maximal involvement of the cochlear capsule by the otosclerotic process.

Evaluation of several instances with non-otosclerotic lamellar bone filling the scala tympani in contact with the otosclerotic focus shall wait until more cases with comparable cases are obtained

TABLE 4 Schematic representation of the portion of the endosteum involved by otosclerosis with accompanying audiograms to show bone conduction thresholds as measured by ASA standards

Note that in Case 7 the upper two coils but not the basilar turn are involved. The hearing in this case is good. Case 11 represents one of two cases in our series in which only the basilar turn was involved, and the BC threshold was considerably elevated.

TABLL 3 *Schematic representation of the endosteum involved by otosclerosis with accompanying audiograms to show bone conduction thresholds as measured by ASA standards*

Note that only the basilar turn is involved and that the thresholds are all good.

Surgical attempts to correct the sensori-neural loss, or prevent its progression have been made by W. House (1969). According to the concept of Goodhill (1963) he opened the obliterated round window in several cases. This failed to improve the hearing. Suspecting that a massive otosclerotic lesion visible on X rays, might be constricting the internal auditory canal he also opened this through the middle fossa route. These results likewise were not encouraging. Recently, he has attempted to improve the blood supply to the cochlea by thinning the cochlear capsule and transplanting it to the tensor tympani muscle (1967). This procedure was based on

TABLE 6. Schematic representation of the portion of the endosteum involved by otosclerosis with accompanying audiograms to show bone conduction thresholds as measured by ASA standards

Note that Case 20 is one of two in our series in which only the basilar coil is involved and the BC threshold is considerably elevated. Note that in Case 26, although the basilar coil is not involved, the internal auditory canal is.

TABLE 5 *Schematic representation of the portion of the endosteum involved by otosclerosis with accompanying audiograms to show bone conduction thresholds as measured by AS1 standards*

Note that either the basal coil and one other coil are involved, or there is involvement of the internal auditory canal. All but Case 14 show a significant increase in the BC threshold

the findings of Rüedi (1966) who has reported vascular shunts between the spiral ligament and the otosclerotic focus. Effectiveness of this attempt has yet to be determined as insufficient time has passed since the intervention was carried out.

To rule out presbycusis as a possible cause of increased loss in cases with cochlear involvement the ages were compared with those individuals with oval window otosclerosis but no cochlear involvement (Table 1). It was found that the age spread was almost identical in the two groups, with

TABLE 6. Schematic representation of the portion of the endosteum involved by otosclerosis with accompanying audiograms to show bone conduction thresholds as measured by ASA standards

Note that Case 20 is one of two in our series in which only the basilar coil is involved and the BC threshold is considerably elevated. Note that in Case 26, although the basilar coil is not involved, the internal auditory canal is.

the average in the mid sixties. The patient with the most extensive otosclerotic lesion and total absence of hearing was 54 years old (illustrations 24 and 2a in Table 6)

Table 2 shows composite audiograms comparing the bone conduction thresholds of individuals with otosclerosis limited to the footplate and vestibule and with those with cochlear otosclerosis.

Comparison of these two composite audiograms indicates that the sensorial neural loss in those individuals with involvement of the endosteal bony layer of the cochlea by otosclerosis is greater than in those in which the lesion is limited to the footplate and vestibule.

An attempt was made to correlate the area of the cochlea involved by otosclerosis and the amount of hearing loss and configuration of the audiogram. No pattern could be ascertained that produced a characteristic audiometric curve. It was noted however that if the basal coil of the cochlea plus one other coil or the internal auditory canal was involved by the otosclerosis, there was more apt to be a sensorial neural loss (Tables 5 and 6). In observing Tables 3 and 4 it will be noted that in no case was the spiral ligament area of the basal coil plus one other coil involved. These patients for the most part have relatively good bone conduction thresholds with the exception of case No. 13 where it was depressed to 40 dB.

If we examine case 14 through 26 (Tables 5 and 6) we find that in most of the cases the basal plus one or more other coil was involved by the otosclerosis. In all but one of these cases, the bone conduction level was considerably depressed. An exception is case 18 in which the internal auditory canal alone was involved. Another exception is case 26, where the internal auditory canal plus the two apical turns were involved. It would appear from these illustrations that if the basal turn and/or the internal auditory canal plus one or more of the other turns of the cochlea are involved there is more likely to be a sensorial neural impairment.

About half of the cases exhibited involvement by otosclerosis of the endosteal layer of the cochlea. Correlation of the audiometric bone conduction tests indicate that when there is endosteal layer involvement there is more apt to be depression in the bone conduction threshold irrespective of the age of the patient.

5 DISCUSSION

A panel discussion on sensori-neural deafness in otosclerosis at the American Otological Society (1966, *Annals of Otol Rhinol Laryngol*) summarized the present status of the conception of labyrinthine, or cochlear otosclerosis. The 13 participants based their presentations, a total of 276 cases with 489 ears, partly on personal observations, partly on studies of extant collections.

Hansen and Reskle-Nielsen (1965) emphasized that the histological measures presently available for processing human temporal bones are often inadequate to establish, beyond doubt, their intravital correlates. Friedman (1968) pointed to the technical limitations when interpreting morphology. Oseous changes have been analyzed in detail in past years since Politzer (1892) described the pathologic entity of otosclerosis. The status of the sensory end organs has been more difficult to evaluate. Many of the descriptions of atrophic lesions have to be disregarded as representing merely the results of unsatisfactory preservation, due to delay between death and processing, and other factors. Imponderabilia played their role in the findings of the most distinguished observers. Lange (1926) pointed out that Wittmaack infrequently found pathological inner ears while Manasse saw them extraordinarily often.

In a preceding section histopathological changes were described in single regions of the ear. The following survey correlates these findings with data of the literature.

The middle ear is infrequently discussed. It is always taken for granted that the metaplastic process is restricted to the bone of the otic capsule.

The tegmen was involved in our material in only one specimen by penetration from the direction of the superior semicircular canal. Malou (1940) observed foci in the tympanic tegmen.

Manasse (1917) enumerated the regions where otosclerosis oversteps the normal boundaries of capsular bone: tympanic cavity membrane of the round window, inner acoustic meatus, and finally spaces inside the osseous labyrinth. The body of the temporal bone outside the otic capsule contains congenital fissures, brought into causal connection with the otosclerotic area (discussion see Helemen, 1933). The most prominent run from the bottom of the niche of the round window to the base of the posterior crista. A number of these formations were seen in our material with no relation between the fissures and otosclerosis.

Politzer (1894) quoted the case of Katz and Habermann with osteoporotic changes in the head of the malleus, and in the body of the incus. The

the average in the mid sixties. The patient with the most extensive otosclerotic lesion and total absence of hearing was 54 years old (illustrations 24 and 25 in Table 6)

Table 2 shows composite audiograms comparing the bone conduction thresholds of individuals with otosclerosis limited to the footplate and vestibule and with those with cochlear otosclerosis

Comparison of these two composite audiograms indicates that the sensorineural loss in those individuals with involvement of the endosteal bony layer of the cochlea by otosclerosis is greater than in those in which the lesion is limited to the footplate and vestibule.

An attempt was made to correlate the area of the cochlea involved by otosclerosis and the amount of hearing loss and configuration of the audiogram. No pattern could be ascertained that produced a characteristic audiometric curve. It was noted, however, that if the basal coil of the cochlea, plus one other coil or the internal auditory canal was involved by the otosclerosis, there was more apt to be a sensorineural loss (Tables 5 and 6). In observing Tables 3 and 4 it will be noted that in no case was the spiral ligament area of the basal coil plus one other coil involved. These patients for the most part have relatively good bone conduction thresholds with the exception of case No. 13, where it was depressed to 40 dB.

If we examine case 14 through 26 (Tables 5 and 6) we find that in most of the cases the basal plus one or more other coil was involved by the otosclerosis. In all but one of these cases, the bone conduction level was considerably depressed. An exception is case 18, in which the internal auditory canal alone was involved. Another exception is case 26 where the internal auditory canal plus the two apical turns were involved. It would appear from these illustrations that if the basal turn and/or the internal auditory canal plus one or more of the other turns of the cochlea, are involved, there is more likely to be a sensorineural impairment.

About half of the cases exhibited involvement by otosclerosis of the endosteal layer of the cochlea. Correlation of the audiometric bone conduction tests indicate that when there is endosteal layer involvement there is more apt to be depression in the bone conduction threshold, irrespective of the age of the patient.

5 DISCUSSION

A panel discussion on sensori-neural deafness in otosclerosis at the American Otological Society (1966, *Annals of Otol Rhinol. Laryngol.*) summarized the present status of the conception of labyrinthine or cochlear otosclerosis. The 13 participants based their presentations, a total of 276 cases with 489 ears, partly on personal observations, partly on studies of extant collections.

Hansen and Reskie-Nielsen (1965) emphasized that the histological measures presently available for processing human temporal bones are often inadequate to establish, beyond doubt, their intravital correlates. Friedman (1968) pointed to the technical limitations when interpreting morphology. Oseous changes have been analyzed in detail in past years since Politzer (1892) described the pathologic entity of otosclerosis. The status of the sensory end organs has been more difficult to evaluate. Many of the descriptions of atrophic lesions have to be disregarded as representing merely the results of unsatisfactory preservation, due to delay between death and processing, and other factors. Imponderabilia played their role in the findings of the most distinguished observers. Lange (1926) pointed out that Wittmaack infrequently found pathological inner ears while Manasse saw them extraordinarily often.

In a preceding section histopathological changes were described in single regions of the ear. The following survey correlates these findings with data of the literature.

The middle ear is infrequently discussed. It is always taken for granted that the metaplastic process is restricted to the bone of the otic capsule.

The *tegmen* was involved in our material in only one specimen by penetration from the direction of the superior semicircular canal. Mialan (1940) observed foci in the tympanic tegmen.

Manasse (1917) enumerated the regions where otosclerosis oversteps the normal boundaries of capsular bone: tympanic cavity, membrane of the round window, inner acoustic meatus, and finally spaces inside the osseous labyrinth. The body of the temporal bone outside the otic capsule contains congenital fissures brought into causal connection with the otosclerotic area (discussion see Helemen, 1933). The most prominent run from the bottom of the niche of the round window to the base of the posterior crista. A number of these formations were seen in our material with no relation between the fissures and otosclerosis.

Politzer (1891) quoted the case of Kalt and Habermann with osteoporotic changes in the head of the malleus, and in the body of the incus. The

large ossicles have been repeatedly described to be a site of otosclerotic changes. These were not found in our material.

Longenital stapes fixation (Kelemen 1943, Altmann 1949) causing labyrinthine hearing defects, was discussed by Shambaugh (1952). House and Hildyard (1958) found cochlear involvement in some of these cases manifested predominantly in higher frequencies. Richards (1964) found this condition in a case with rubella.

Among the nervous elements the nerve of Jacobson seems to have been entirely disregarded as to a role in the hearing mechanism except indirectly as a source of tinnitus. According to Lempert (1946) vascular changes on the promontory could be a source of ear noises. As no role in the hearing mechanism was assigned to this nerve cases where the walls of its canal were partly or completely transformed by otosclerosis are in this report simply enumerated.

The relations of the facial nerve to otosclerotic foci were studied by Kelemen and Linthicum (1965). Jones (1941) was the only author who included participation of the facial into the otosclerotic syndrome declaring facial paralysis a most notable symptom of the disease. Never mentioned before this finding was equally ignored after Jones' publication.

The most conspicuous picture of vestibular participation showed the osseous base of the end organs with their respective cribriform plates transformed to otosclerotic bone completely surrounding the nerve fibers. No blockage or even compression was seen under the microscope. The functional aspect of the condition will be discussed below.

Slebenmann (1899) arrived at the conclusion that participation of the canal of the utricle-ampullar nerve in the metaplastic process leaves the nerves and fibrous surroundings unaltered with the ampulla remaining free of changes and without functional disturbance. On the other hand he explained Menière attacks, in otosclerosis, by ruptures of partitions in the vestibule causing sudden changes in pressure and position. This concept was taken up many decades later by several writers.

Frequent incorporation of the cisternal wall in the otosclerotic focus makes the macula of the sacculus eminently vulnerable.

Rüttin (quoted by Ruedi *Acta*, 1964) indicated that vertigo may occur due to foci located in vicinity of the ampulla. Newby (1958) mentioned occasional destruction of some nerve fibers in the vestibulum. Shambaugh (1960) saw the same when the lumen of a semicircular canal was reached.

As is the case with the facial nerve and its canal even intimate contact with otosclerosis left the vestibular nervous apparatus indifferent. A fact hard to bring into harmony with the assumption of any noxious material secreted, often during decades, by the otosclerotic mass surrounding the nerves.

The osseous semicircular canals are quoted as one of the predilectional sites of otosclerotic transformation. Several examples showed penetration of the endosteal layer. Here the mechanism was the same as described for

the innermost layer of the bony cochlear wall. But even complete encircling did not result in compression of the membranous canal.

In no case did otosclerotic lesion reach the vestibular aqueduct.

Assault against the cochlea comes from the center and from the periphery: the former leads directly into the modiolus and proceeds from the direction of the cribriform plate or from the interscalar septa. Fowler (1919) illustrated extension into the septum between basal and middle turn. Allmann (1952) thought that ingrowth of otosclerosis into the septa, particularly between basal and middle turn, interferes with the vascular supply of the cochlea. Instances with invasion of the modiolus through the cribriform plate were rare. Where the interscalar septa have been invaded the modiolus was hardly reached. All in all direct damage to the nervous apparatus in the modiolar canal, e.g., compression, plays a minor role—in sharp contrast to exposure of the nerve in the internal meatus.

Contact of the otosclerotic focus with the external wall of the cochlear turn is a cardinal point for potential damage through influence exerted on the anchoring system of the basilar membrane. Goodhill (1961) emphasized that massive intracochlear lesions interfere with proper basilar membrane dynamics.

The boundary between original and metaplastic bone was always sharp as found by Nager and Meyer (1952) by polarized light (standard in the present investigations); they stated that transitions between old and otosclerotic bone do not exist.

As practically every otosclerotic focus contains distinctly separated spongy and sclerotic portions, it seemed to be of interest to see whether one or the other component is the first to reach the capsular wall. Tabulations along this line failed to show predominance of one or the other. Shambaugh's (1966) laminagrams showed, in half of the patients, with the possibility of cochlear otosclerosis, a spongy or partly recalcified focus. We concur with the thesis of Wolff (1964): it is impossible to regard the different types of tissue in which otosclerosis presents itself as successive stages in the development of the disease.

The atlas of Voss (1917) illustrates the focus reaching the lumen of the cochlea or vestibulum after traversing the capsule (Fig. 52). His description of the process follows: On the external wall of the spiral ligament one observes thick, globular connective tissue prominences; they can protrude far into the lumen of the cochlear duct. Hydroptic degeneration of the spiral ligament is never lacking; the coarse band of connective tissue lining the regular wall of the cochlear turn is interrupted by many vacuoles, partly rhombic, partly triangular, empty or filled with finely granulated masses or mucus. Detachment of the endosteum by the advancing otosclerotic mass was clearly shown by his artist (Fig. 10a of the atlas) who, however, represented the inner surface of the endosteum as being smooth, not deformed. Lange (1926) on the other hand saw the endosteum, wherever it was reached by the focus, more or less thickened. Shambaugh (1960) observed

the same when the lumen of a semicircular canal was reached Schuknecht, McGee, Igarashi, Fujita, and Davison (1964) saw adjacent to the advancing otosclerotic lesion, atrophy of the spiral ligament Rüedi (1964) gave several illustrations of the otosclerotic focus contacting the spiral ligament.

According to Werner (1931) the endosteal layer is lacking at the cochlear tip It is questionable whether this circumstance facilitates otosclerotic penetration in this area. Lawrence (1956) considered the extant information regarding the elements around the spiral ligament as insufficient. In agreement we found data regarding the elements around the spiral ligament inadequate and regarding the anchoring of the spiral ligament to the bone conspicuously scarce

Regarding the anchoring of the spiral ligament to the osseous wall of the cochlear capsule, it is not easy to gain a clear picture Neubert (1900) complained about the lack of information on the manner of the axial anchoring and about lack of data on the connection between the spiral ligament and the bony wall This wall carries (Richany Anson and Bast, 1960) through the proximal half of the basal turn a smaller secondary plate namely the lamina spiralis secundaria, opposite the osseous spiral lamina, which becomes gradually lower and finally disappears It is possible that this spine forms the basis of the otosclerotic exostoses (called sometimes enostoses) protruding almost exclusively,—and, even so, rather infrequently—into the cochlear scala of the basal turn Held (1926) emphasized the importance of conditions in this region and explained how tension of the basilar membrane depends on its anchoring in the spiral ligament

Yet information on anchoring of the spiral ligament to the osseous capsule is decisive Changes made by the advancing otosclerotic mass result in deformation loosening of the basilar membrane with subtle deformation in the architecture of the Corti papilla albeit hitherto not verified under the microscope

Held (1926) gave the following description Among the cells of the walls of the two perilymphatic scales only the connective tissue cells of the spiral ligament show conspicuous histologic particularities, occupying the inner part from the insertion of the basilar membrane by a tightly stretched net work of fibers The external part broadening continuously is compact and shows all endosteal characteristics of a connective tissue mass in its transition into the bony cochlear capsule itself In the inner part of the spiral ligament, connective tissue cells rich in plasma form smaller and larger nests, finely granulated and intimately connected to the walls of the vessels In the inner part of the spiral ligament another arrangement gains importance namely the insertion of the basilar membrane The fibers of the spiral ligament are at the prominent inner ledge still densely compressed here its radiating fibers dissolve into a tightly stretched reticulum with very wide meshes, in which the radial fibers are held together everywhere by transverse and oblique connecting fibers

Breschet (1836) found a gelatinous substance inserted between the bony

wall and the basilar membrane Henle (1866) was unable to separate the periosteum from the bone without loosening fragments from the most superficial bony lamellae Schwabe (188) found the much thickened external wall of the cochlear duct solidly connected with the periosteum. Venbert was able to loosen the periosteum from the bone on the one side and from the external surface of the spiral ligament without difficulty. According to his description the lamina spiralis secundaria, serving as attachment of the spiral ligament to the bony cochlear wall, is composed of a system of richly branched bony spines and plates.

Rehder (1960) experienced the greatest difficulty in opening a cochlear canal as its lining of a tough, thin membrane adhered only loosely to the bone.

Venbert summarized the mechanism of the peripheral anchoring in the following way. The attachment of the basilar membrane is secured by the connective tissue wedge of the spiral ligament, which is divided, according to the structure of its cellular fibrous material, into three zones not sharply delimited against each other. The inner portion, fanning out wedge-like contains a filling mass the fanlike deploying basilar fibers. In the median layer interwoven and anastomosing fibers create a honeycomb network with meshes, which become richer in fluid the more they approximate the top of the cochlea. The third border layer follows outward, as a comparatively narrow dense plate rich in cells, its network forming a vertical lattice. The adjacent periosteum is distinctly thicker in the extent of the spiral ligament. Its fiber bundles meet in acute angles, crossing and penetrating each other and run, generally in longitudinal direction along the cochlear canal. Differences in the firmness of the single constituents at the borders of the divisions guarantee deformability of the spiral ligament.

This deformability a shifting of the plates along each other offers ample explanation for changes incurred by the approach of the otosclerotic mass.

According to Rüdell (1964) the spiral ligament is lower and is loosely built at its boundary to the tympanic scala, whereas the surface against the vestibular scala is covered by an end thel-like layer.

Turning to the changes of this apparatus at otosclerotic foci, one has to consider that at the cochlear tip (frequently invaded by the otosclerotic focus) the nodular layer may be lacking—Werner (1931) and Serter (1966) described the nodular layer to be perfectly avascular. No vascular pathway connects the endosteal and the enchondral layer according to present knowledge. A vascularity might have to do with poor resistance against the advancing otosclerotic mass.

Schlemm (1811) observed a serous exudate in the perilymphatic space of the cochlea at extension of otosclerosis to the endosteum. This observation might have offered the basis for his concept according to which metal plates liberated by the pathologic bone diffuse through the endosteum into the perilymph and endosteum of the cochlea, with damage to the cochlear nerve endings. Going one step farther he assumed a serous labr

the same when the lumen of a semicircular canal was reached. Schuknecht, McGee, Igarnahil, Fujita and Davison (1964) saw adjacent to the advancing otosclerotic lesion, atrophy of the spiral ligament. Rüdel (1964) gave several illustrations of the otosclerotic focus contacting the spiral ligament.

According to Werner (1931) the endosteal layer is lacking at the cochlear lip. It is questionable whether this circumstance facilitates otosclerotic penetration in this area. Lawrence (1956) considered the extant information regarding the elements around the spiral ligament as insufficient. In agreement we found data regarding the elements around the spiral ligament inadequate, and regarding the anchoring of the spiral ligament to the bone conspicuously scarce.

Regarding the anchoring of the spiral ligament to the osseous wall of the cochlear capsule it is not easy to gain a clear picture. Deubert (1940) complained about the lack of information on the manner of the axial anchoring and about lack of data on the connection between the spiral ligament and the bony wall. This wall carries (Richany, Anson and Bast 1960) through the proximal half of the basal turn a smaller secondary plate, namely the lamina spiralis secundaria opposite the osseous spiral lamina which becomes gradually lower and finally disappears. It is possible that this spine forms the basis of the otosclerotic exostoses (called sometimes enostoses) protruding almost exclusively—and even so, rather infrequently—into the cochlear scala of the basal turn. Held (1926) emphasized the importance of conditions in this region and explained how tension of the basilar membrane depends on its anchoring in the spiral ligament.

Yet information on anchoring of the spiral ligament to the osseous capsule is decisive. Changes made by the advancing otosclerotic mass result in deformation, loosening of the basilar membrane with subtle deformation in the architecture of the Corti papilla, albeit hitherto not verified under the microscope.

Held (1926) gave the following description. Among the cells of the walls of the two perilymphatic scales only the connective tissue cells of the spiral ligament show conspicuous histologic particularities, occupying the inner part from the insertion of the basilar membrane by a tightly stretched net work of fibers. The external part broadening continuously is compact and shows all endosteal characteristics of a connective tissue mass in its transition into the bony cochlear capsule itself. In the inner part of the spiral ligament connective tissue cells rich in plasma form smaller and larger nests, finely granulated and intimately connected to the walls of the vessels. In the inner part of the spiral ligament another arrangement gains importance, namely the insertion of the basilar membrane. The fibers of the spiral ligament are at the prominent inner ledge still densely compressed; here its radiating fibers dissolve into a tightly stretched reticulum with very wide meshes, in which the radial fibers are held together everywhere by transverse and oblique connecting fibers.

Breschet (1836) found a gelatinous substance inserted between the bony

of the fibrils each fiber is transformed into a rosary-like structure. Possibly this process is repeated whenever the focus penetrates the endosteal bone and produces the fragmentation into a rosary like formation, as described in detail in Section 3. This fragmentation represents the correlate in the dimensions of the light microscope. The description of Chevance is valid to the otosclerotic focus in any location, and so it is remarkable that this enlarged form should be adopted only when contact with cochlear space is achieved. If so this phenomenon represents the most remarkable single observation hitherto formulated on the process of penetration.

Holleman and Harrit (1967) found otosclerotic involvement of the endosteal layer with regressive changes in stria and spiral ligament, such as atrophy fibrosis, hyalinization however abnormal vascular shunts were not a significant feature.

Siebenmann (1911) observed that often merely a very thin septum divides the perilymphatic spaces of the cochlea from the large lymphatic spaces within the spongy bone. Examples of this arrangement were given in Section 3. On the other hand, atrophy of osseous tissue, of the vascular stria, of cells and nerves in the cochlea, as described by Mayer (1917) and Gray (1934) and confirmed by Nager and Fraser (1938) depend too much on the hazards of histological processing to be built definitively into the microscopic picture of labyrinthine deafness. According to this concept, a cochlea assaulted by otosclerosis would offer a picture of total demolition this obviously is not the case.

Lawrence (1966) declared the arcade vessels beneath the basilar membrane to be the nutrient vessels of the organ of Corti. According to this concept it is not the stria system which feeds the hair cells, and therefore stria-damage by the focus, approaching through the capsular wall, would not cause sensori-neural deafness. On the other hand, warping of the arcade vessels themselves might endanger the function of the organ of Corti.

In the entire process of otosclerotic penetration of the cochlea, it remains noteworthy that the contours of the intracochlear space are so widely preserved. Frequently only some flattening of the concave bony contour is seen, and definite penetration by exostotic protuberances is restricted largely to the basal turn. The penetrating power peters out somehow seemingly there has to be capsular bone present to be transformed, and without this nourishment, otosclerosis loses its momentum. This might well be what Brunner called atrophy of the advancing edge a phenomenon we did not succeed in identifying.

The inner meatus frequently is a veritable showplace of otosclerotic proliferation resulting in coarse alterations of the lumen. Concentric narrowing or excrescences into the lumen impinge on the nerve. Here lies possibly the core of the problem of cochlear deafness. Manasse (1917) considered constriction of the lumen of the inner meatus by otosclerotic bone a serious influence on the function of the 8th nerve. The normally smooth wall of the

rhinitis, due to metabolites passing from the otosclerotic focus into the internal ear Lindsay (quoted by Carhart 1963) similarly assumed early labyrinthitis as basis for invasion of the tympanic scala. One might recall that not merely was the existence of some special secretory product of the otosclerotic mass postulated, but its origin itself has been attributed to endocrine abnormalities (Escal quoted by Holz, 1960).

Attention has been frequently directed to the role of the *vascular stria*. It is to be remembered that Fischer (1925) saw many variations in its normal histological picture frequently it is hard to decide whether one deals with normal conditions or pathologic changes.

Changes in the stria vascularis caused by the approaching focus, as a possible source of lesions in the organ of Corti were mentioned by Ruitin (quoted by Siebenmann 1911) Mayer (1917) Lange (1926) Wolff (1950) Rüedi (1964).

Manasse (1912) saw at the lower end of the stria thick, round, fibrous prominences of dubious vascular origin occasionally jutting far into the lumen of the cochlear duct. Mayer (1917) reported engorgement venous stasis in the vascular stria and thought it responsible for functional damage. Rüedi (1964) observed circumscribed increase in the vascular loops and proliferation of the epithelium of the stria while Benitez and Schuknecht (1962) showed (Fig. 3) otosclerosis extending to the endosteum and creating atrophy of the spiral ligament. Schuknecht, Igarashi, Fujita and Davidson (1964) saw atrophy of the spiral ligament with connective tissue thickening adjacent to otosclerotic lesions.

Penetration of the endosteum is the last step before the otosclerotic focus reaches the immediate neighborhood of the cochlear space. Lange (1926) saw the endosteum more or less thickened where it was reached by the focus. Shambaugh (1950) noted formation of a thin layer of amorphous collagenous material beneath the adjacent connective tissue after otosclerosis had absorbed the endosteal layer of the bony capsule. Manasse (1912) explained how the walls of the cochlear duct undergo hydropic degeneration at the spiral ligament: the coarse connective band lining the concavity of the capsule becomes permeated by many partly rhombic spaces, which are either empty or show finely pulverized or mucous content.

The final step penetration of the otosclerotic focus itself through the endosteal bone and the periosteum, was clearly illustrated by Manasse (1917) in his atlas (see above). This picture is remarkably similar to the numerous cases where the focus, in its so-called predilectional location "hesitates" (to apply the appropriate expression of Hough, 1964) to step across the annular ligament.

The otosclerotic tissue itself may go through a retrograde step when approaching the cochlear space. According to Brunner (1952) the otosclerotic bone approaching the endosteum frequently becomes atrophic. Chevaunce (1962) saw under the electron microscope at the stage of formation of the focus, disappearance of the collagenous tissue by a process of fragmentation.

the delicate elements of the organ of Corti. Immediately under the perosteum there is frequently only a thin septum separating large lymphatic spaces from the otosclerotic area. When this septum breaks, labyrinthine pressure and position changes appear. Ruptures initiating sudden changes may explain hearing losses. Corti cells, stria vascularis, nerves, windows remain intact. Vertigo appearing with the hearing loss can be of the same origin. Menière attacks, mild or apoplectic form, could be sufficiently explained by this mechanism, offering a monistic interpretation for cochlear and vestibular damage.

In the three quarters of a century since the promulgation of this concept, there have been endless deliberations. Frequently new "theories" are presented, omitting sometimes to mention the initiator. Clash of opinions was sharp throughout this long period. Guild (1944) championed the opposition.

"Atrophy of cochlear nerve fibers or of the organ of Corti does not occur more often in ears with otosclerotic areas than in ears free of otosclerosis." He was unable (as quoted by Ash and Raum, 1956) to accept any influence of otosclerosis on the cochlear apparatus. A similar stand was taken by Glorig and Gallo (1962) who found that otosclerosis does not increase sensori-neural hearing loss above that to be expected in the general population. Runge (1976) explained that combination of the effect of stapedial ankylosis and inner ear deafness may be observed with a relatively innocuous neuro-epithelial degeneration. Shambaugh (1959) observed that labyrinthine otosclerosis with cochlear loss of otosclerotic origin without stapes fixation is probably more common than generally thought. He later (1966) progressed to the opinion that stapedial and cochlear invasion are equally frequent. Rollin (1910) albeit assuming hydrops with the focus reaching the endosteum, found that Corti and vestibular end organs are left undamaged. Carhart (1962) mentioned that some of the progressive hearing losses now classified as sensori-neural deficits are probably the result of labyrinthine otosclerosis without accompanying stapes ankylosis.

In the near past, attempt toward an approach by chemical analysis appeared, not practicable in the time of Siebenmann. Bullstein, Eley, Rauch, and Roestlin (1960) wanted to objectivate toxic damage by analysis of the perilymph of operated otosclerotics. Sodium and potassium turned out to be unchanged. Alkali phosphatase was increased. Besides the bone process, vascular activity within the focus was considered as potentially responsible. Rüdell (1962) saw for the theory of Siebenmann a new explanation in the investigations of Naftalin and Harrison (survey 1966) on active circulation of the labyrinthine fluids. Maurer (1962) found in different regions of otosclerotic bone decreased mineralization. He concluded (1967) that decrease in mineral content and increase in nitrogen content and in activity of alkaline phosphatase point to a higher than normal participation of fibril content in the web-like bone. Rüdell, Sanz and Fisch (1964) confirmed, in perilymph withdrawn in the course of stapedectomies, the presence of alkali phosphatase with decrease of calcium and increase of

inner meatus becomes frayed, torn up over the otosclerotic product the dura is engorged, producing a "Schwartz sign" in the inner meatus. Circular stenosis appeared in our material infrequently but often flat or spiny even clawlike protrusions reached deep against the nerve. The possibly far reaching functional damage is hard to judge.

The fundus of the inner acoustic meatus is surrounded by several layers of periosteal lamellae. The enchondral layer follows the contour of the periosteal sheath while an endosteum—continuation here of the dural lining of the meatus—is hardly discernible. It is possible that the lack of it is responsible for the exuberant proliferation of otosclerotic excrescences in this location.

Pneumomas in the inner meatus are most numerous along the frayed edges of the protruding focus and less numerous along the smoother parts of the dural lining. Predominantly they aggregate along lesions of spongy, vascular nature. Without suggesting any causal connection between otosclerosis and proliferation of pneumomas, one might recall a number of "monistic" theories according to which vascular etiology underlies all inner ear changes in otosclerosis. Ever present hyperemia in these cases with invasion by the focus, might offer richer material to create similar formations of vascular origin. In the inner meatus, in his case rebuilt by Paget's disease Tamari (1942) found innumerable pneumomas in the sheath of the nerve. Increased irritation by the formerly smooth now ragged surface may enhance their development.

Influence exerted by the otosclerotic mass through secreted products was most peremptorily formulated by Manasse (1912) who declared that atrophy in the wake of otosclerosis is a regular consequence *independent of the extent or localization of the osseous lesion*. Cray (1917-1932) echoed this conception postulating degeneration of the cochlear nerve independent of the fixation of the stapes or of any osseous change in the capsule of the labyrinth. *Deafness occurred before the stapes is fixed* due to primary damage to the cochlear nerve. This idea claims a single developmental source for stapedial and cochlear deafness, caused by purely mechanical obstruction and metabolic damage. Moritz (1935) accepted vegetative origin for half of the cases where otosclerosis was accompanied by inner ear deafness.

Siebenmann's initial concept (1899) was somewhat less transigent. The focus has to reach a certain degree of change before a toxic substance is produced in sufficient concentration to cause functional damage. According to his teaching the course of events can be reconstructed in the following way: when the focus reaches the endosteum a serous transudate occurs within the perilymphatic cochlear spaces. The metaplastic bone liberates metabolites which by way of the transudate reach the peri- and endolymph spaces of the cochlea with damage to the nervous apparatus. To the changes in pressure and density of the labyrinthine fluid caused by advance of the focus, chemical alterations are added that end in nutritive damage to

the delicate elements of the organ of Corti. Immediately under the perioticum there is frequently only a thin septum separating large lymphatic spaces from the otosclerotic area. When this septum breaks, labyrinthine pressure and position changes appear. Ruptures initiating sudden changes may explain hearing losses. Corti cells, stria vascularis, nerves, windows remain intact. Vertigo appearing with the hearing loss can be of the same origin. Menière attacks, mild or apoplecticiform, could be sufficiently explained by this mechanism, offering a monistic interpretation for cochlear and vestibular damage.

In the three quarters of a century since the promulgation of this concept, there have been endless deliberations. Frequently new "theories" are presented, omitting sometimes to mention the initiator. Clash of opinions was sharp throughout this long period. Guild (1944) championed the opposition.

Shambaugh (1959) observed that labyrinthine otosclerosis with cochlear loss of otosclerotic origin without stapes fixation is probably more common than generally thought. He later (1966) progressed to the opinion that stapedial and cochlear invasion are equally frequent. Rollin (1910) albeit assuming hydrops with the focus reaching the endosteum, found that Corti and vestibular end organs are left undamaged. Carhart (1962) mentioned that some of the progressive hearing losses now classified as sensori-neural deficits are probably the result of labyrinthine otosclerosis without accompanying stapes ankylosis.

In the near past, attempts toward an approach by chemical analysis appeared, not practicable in the time of Siebenmann. Wallstein, Kley, Rauch, and Koettlin (1966) wanted to objectivate toxic damage by analysis of the perilymph of operated otosclerotics. Sodium and potassium turned out to be unchanged. Alkaline phosphatase was increased. Besides the bone process, vascular activity within the focus was considered as potentially responsible. Riedl (1962) saw for the theory of Siebenmann a new explanation in the investigations of Wallstein and Harrison (survey 1966) on active circulation of the labyrinthine fluids. Maurer (1962) found in different regions of otosclerotic bone decreased mineralization. He concluded (1967) that decrease in mineral content and increase in nitrogen content and in activity of alkaline phosphatase point to a higher than normal participation of fibril content in the web-like bone. Riedl, Sanz and Fisch (1964) confirmed in perilymph withdrawn in the course of stapedectomies, the presence of alkaline phosphatase with decrease of calcium and increase of

potassium and protein correlation of potassium and protein increase with preoperative bone conduction impairment could be demonstrated.

Sulfhydryl groups were claimed as indication (Chevance 1964) of respectively destructive or constructive phases within the pathologic bone

Schindler and Schnierer (1966) did not find any statistically verifiable difference between perilymph from otosclerotics and perilymph from patients with tympanosclerosis, congenital stapes ankylosis, Menière etc. Concentrations of sodium potassium and lactic acid dehydrogenase in perilymph of otosclerotics have been found by Silverstein and Schuknecht (1966) to be similar to serum levels

These few examples are evidence that the need is felt to create a solid basis for the persistently quoted concept of Siebenmann Chevance (1962) expressed the hope that clarification can be expected in the not-too-distant future Existence of substances released into the labyrinthine fluids, as cause of sensori neural loss in otosclerosis, was accepted as a working hypothesis by Altmann Kornfeld and Shea (1966) But in the words of Lawrence (1966) much more information is needed on the dynamics of the normal membranous labyrinth before it can be said that a sensori neural hearing loss can be produced by biochemical changes resulting from otosclerosis he declared that it is not known whether chemicals toxic to the organ of Corti might be exuded by an otosclerotic focus Charachon (1967) reported on the explosion like multiplication of studies in chemistry of the labyrinth fluids in the last decade

Watson and Tolan (1949) postulated postmortem examination to be the only proof that a nerve deafness is indicative of otosclerosis Brunner (1952) wanted microscope studies continued as the final solution the problem will be solved by pathology and not from surgery Mueller (1959) declared that only morphologically verified changes in the membranous labyrinth can decide as to the causes of inner ear damage in otosclerosis Bosstra (1960) acknowledged histopathology as the only absolute demonstration of stapedial ankylosis in one ear and cochlear involvement in the other Shambaugh (1960) offered clinical signs for suspecting cochlear loss without stapes fixation he emphasized, however that there is no reliable method other than histopathology or at least X ray to diagnose the condition Altmann (1962) considered the discrepancy between neurosensory hearing loss, and lack of histological evidence to support a similar change as disturbing Carhart (1963) found that otosclerotic temporal bone specimens explaining untraditional audiological findings were still in limited supply According to Derlacki and Valvassori (1965) the typical picture of labyrinthine otosclerosis has not been the object of intensive study as yet the histological impasse may take years to resolve In final analysis otosclerosis as a clinical entity must find its decisive evaluation in the histopathologic documentation

Contemplation of the critical area where original and metaplastic bone meet raises the question whether a sector exists as mentioned above between

the two, a no-man's-land carrying signs of approaching destruction. Pre-otosclerotic changes as described by Brunner are characterized by overproduction of precollagenous substance and primitive bone. In the present material, capsular and otosclerotic bone met with a very sharp boundary. This sharp outline was seen by Chevance (1962) even at a magnification of 60,000 under the electron microscope. Fingerlike protrusions are the usual form of propagation of otosclerosis, but the boundary around these is not less sharp. A still normal lamella immediately adjacent to an otosclerotic protrusion does not show any difference from the normal lamella next to it.

The otosclerotic protrusions seem to hit the lamellae generally "head on". This behavior contrasts with the propagation, e.g. of a carcinoma, with its tumor mass penetrating along the lamellae and prying them apart. It remains to be seen whether the above manner of attack can be established as characteristic of otosclerosis.

Rius (1961) found that enchondral and endosteal layers are composed of devitalized, even necrotic bone. This fact does not deter otosclerosis from penetrating both.

As a technical remark it should be mentioned that, regarding elements of the inner ear many reports on "atrophy" can justly be disregarded. The difficulty of obtaining adequate material with added vicissitudes of more or less success in fixation of the specimens for studies on otosclerosis was well known until the change created by the institution of the Bone Banks. Contradictions arose easily. Jones (1941) included labyrinth "atrophy" in the "typical picture of otosclerosis, while Bosatra and others considered the classical picture as one where the inner ear lesion appears only in the latest stages. The present material shows that a similar time sequence cannot be asserted, as the initial assault can well be directed against the cochlear capsule.

After description of pseudo-otosclerosis by Moritz (1935) serious warning appeared concerning simultaneous observations of otosclerosis and inflammatory conditions, with interpretation of serous or other secretions as metabolites liberated by the otosclerotic process (e.g. Dietzel 1938). The difficulty of keeping apart otosclerosis and isolated stapedial ankylosis caused by adhesive processes had already been pointed out by Runge (1928). Goodhill (1966) extensively discussed the "wide range of clinical states which may mimic otosclerosis". Sooy (1960) suggested measures of management of middle ear lesions imitating otosclerosis. Today "pseudo-otosclerosis" can boast an extended literature. Neougar (1965) systematized false otosclerosis. Schuknecht and Gross (1966) warned against identifying sensorineural hearing loss invariably with otosclerosis, as other condition may concur.

The first page of this presentation quoted Krepuha and Krepuska (1936) who declared it impossible to separate labyrinthine deafness, as an otosclerotic damage to the cochlear capsule, from other hearing loss of inner-ear origin.

The difficulty of diagnosing cochlear otosclerosis during life was re-emphasized lately by Shambaugh (1966) who tabulated the situations in which it should be suspected

Polytome laminagraphy with its rapid progress, may offer a valuable correlate to histologic investigation

6 SUMMARY

In 1899 Stebenmann formulated his theory according to which "metabolites," produced by the otosclerotic bone, exercise toxic influence ending in hearing damage. His theory has been adopted by numerous authors down to the very present. No evidence has turned up, under the light microscope to substantiate this concept. Results of the few chemical investigations searching after the special otosclerotic product possibly remain the only ones to deliver arguments in its favor.

Our own material permitted us to tabulate cases with the otosclerotic focus in contact with the osseous cochlear capsule. Statistical evaluation is futile because of the steady arrival of additional material. Similar findings of other investigators give the impression they may form half of the cases especially in higher age groups.

In 101 patients, years after their surgery, not a single instance of the so-called "burned out" focus was observed. It seemed that involvement around the cochlear capsule proceeded to reach in higher ages maximum expansion. Surgical intervention, executed around the stapes did not influence further growth of the focus. The most extended transformation of all parts of the otic capsule was seen in a 77 year-old woman with hearing difficulty since age 18 and total deafness since her 31st year.

Careful observation of the capsular bone adjacent to the advancing focus did not show any structural change in the sense of a "pre-otosclerosis." Nothing spoke for a softening up of the immediate surrounding in front of the advancing focus. This would be obviously one of the effects of metabolites produced by the focus. Breaking through the walls—osseous and fibrous—of the capsule cochlear and vestibular was accomplished by sheer physical force, pressure making the assumption of any other form of violence unnecessary and unwarranted.

No sign of otosclerotic involvement outside the otic capsule as in the large oticles have been encountered. No preponderance of otosclerotic involvement of the fissular region was observed. A modification of the area to be called predilectional site has been suggested by Helemen and Linthicum in 1963. The so-called congenital fissures of the temporal bone encountered frequently described by others as predilectional locations, did not show any connection with the otosclerotic process.

Every otosclerotic focus contained spongiotic and sclerotic portions; the two components were within the focus, generally as sharply divided as was the entire focus from the original bone. Neither of the two can be assigned any preferential role in progression as to age or as to expansion. The terms "young" and "old" focus ask for serious revision, together with the traditionally assumed developmental sequence of the otosclerotic focus.

The difficulty of diagnosing cochlear otosclerosis during life was re-emphasized lately by Shambaugh (1966) who tabulated the situations in which it should be suspected

Polytone laminagraphy with its rapid progress, may offer a valuable correlate to histologic investigation

6 SUMMARY

In 1893 Siebenmann formulated his theory according to which "metabolites," produced by the otosclerotic bone exercise toxic influence ending in hearing damage. His theory has been adopted by numerous authors down to the very present. No evidence has turned up, under the light microscope, to substantiate this concept. Results of the few chemical investigations searching after the special otosclerotic product possibly remain the only ones to deliver arguments in its favor.

Our own material permitted us to tabulate cases with the otosclerotic focus in contact with the osseous cochlear capsule. Statistical evaluation is futile because of the steady arrival of additional material. Similar findings of other investigators give the impression they may form half of the cases especially in higher age groups.

In older patients, years after their surgery, not a single instance of the so-called "burned out" focus was observed. It seemed that involvement around the cochlear capsule proceeded to reach in higher ages maximum expansion. Surgical intervention, executed around the stapes did not influence farther growth of the focus. The most extended transformation of all parts of the otic capsule was seen in a 77 year-old woman with hearing difficulty since age 18 and total deafness since her 27th year.

Careful observation of the capsular bone adjacent to the advancing focus did not show any structural change in the sense of a "pre-otosclerosis." Nothing spoke for a "softening up" of the immediate surrounding in front of the advancing focus. This would be obviously one of the effects of "metabolites" produced by the focus. Breaking through the walls—osseous and fibrous—of the capsule cochlear and vestibular was accomplished by sheer physical force—pressure making the assumption of any other form of violence unnecessary and unwarranted.

Sign of otosclerotic involvement outside the otic capsule as in the large ossicles has been encountered. No preponderance of otosclerotic involvement of the fissular region was observed. A modification of the area to be called predilectional site has been suggested by Kelemen and Linthicum in 1966. The so-called congenital fissures of the temporal bone encountered frequently described by others as predilectional locations, did not show any connection with the otosclerotic process.

Every otosclerotic focus contained spongiotic and sclerotic portions; the two components were within the focus, generally a sharply divided as was the entire focus from the original bone. Neither of the two can be assigned any preferential role in progression as to age or as to expansion. The terms "young" and "old" focus ask for serious revision, together with the traditionally assumed developmental sequence of the otosclerotic focus.

Comparison of the ante mortem bone thresholds with the histopathologic findings has shown, in this material, that the majority of individuals with otosclerotic involvement of the cochlear endosteal layer have an elevated bone conduction threshold. Contrarily, only few individuals in whom otosclerosis remained restricted to the footplate or the vestibulum had a significant increase of the threshold. No correlation between the configuration of the audiogram and the portion of the cochlea involved by otosclerosis was found. However, increase in the bone conduction threshold was observed in the ears, in which the basal turn, and one or more of the other turns, or the inner meatus was involved by otosclerosis.

ZUSAMMENFASSUNG

Siebenmanns Theorie laut welcher otosklerotischer Knochen Stoffwechselprodukte erzeugt, die durch Giftwirkung Hörschaden erzeugen, war 1899 formuliert und fand zahlreiche Anhänger. Unter dem Lichtmikroskop waren keine Beweise aufgetaucht, um diese Theorie zu unterstützen. Ergebnisse chemischer Untersuchungen die nach dem spezifischen otosklerotischen Produkt fahnden, könnten möglicherweise in bejahendem Sinne ausfallen werden.

Berührung zwischen Schneckenkapsel und otosklerotischem Herd war in unserem Materiale in Übereinstimmung mit Befunden, oder wenigstens Vermutungen, anderer Autoren, so häufig gesehen, dass es sich dabei um die grössere Hälfte der Fälle handelte. Dies gilt vor allem für Ältere Altersgruppen. Tabulierung wurde unterlassen, da Einlaufen von weiterem Material häufige Änderungen erfordert.

Auch in ältesten Patienten kam kein einziges Beispiel von einem sogenannten „ausgebrannten“ Herd zur Beobachtung. Es scheint, dass Einbeziehung der Schnecken- und Vorhofkapsel in höherem Alter weiteste Ausbreitung erreicht, sowohl das spongiöse wie das sklerotische Element betreffend. Petistapediale Eingriffe haben das Weiterwachsen des Herdes nicht beeinflusst. Weiteste Einbeziehung aller Teile der Schneckenkapsel war in einer 77 Jahre alten Frau beobachtet, als war seit ihrem 18. Jahre schwerhörig und seit ihrem 27. Jahre vollständig taub.

Die Knochenpartie der Innenohrkapsel, angrenzend an den vordringenden Herd bot keine strukturelle Änderungen dar im Sinne einer sogenannten pre-Otosklerose. Nichts zeugte z. B. von einer Auflockerung gegenüber dem fortschreitenden Herd, ähnlich als man dies als ein Effekt der von dem Herd angeblich erzeugten Cystin Stoffe fordern müsste. Durchbruch von Wandungen, in Schnecke und Vorhof wird durch eine einzige physische Kraft, nämlich Druck, Annahme einer jeden sonstigen Einwirkung erübrigt sich.

Ausserhalb der Innenohrkapsel war keine Spur einer otosklerotischen Umwandlung zu erkennen, so auch nie in den Gehörknöchelchen. Änderung der Bezeichnung „bevorzugter Sitz“ Prädisloktionsstelle“ des Herdes war 1966 von Helemen und Linthicum vorgeschlagen. Sogenannte kongenitale Spalten des Schläfenbeines waren häufig beobachtet ohne Anhaltspunkte sie mit Otosklerose in Bezug zu bringen. Ebensovienig war dies der Fall für die Gewebe die in die fissuläre Gruppierung einbegriffen sind.

Jeder otosklerotische Herd enthielt spongiöse und sklerotische Anteile. Die beiden waren, innerhalb des Herdes so scharf gegeneinander abgegrenzt,

Comparison of the ante mortem bone thresholds with the histopathologic findings has shown in this material that the majority of individuals with otosclerotic involvement of the cochlear endosteal layer have an elevated bone conduction threshold. Contrarily only few individuals in whom otosclerosis remained restricted to the footplate or the vestibulum had a significant increase of the threshold. No correlation between the configuration of the audiogram and the portion of the cochlea involved by otosclerosis was found. However increase in the bone conduction threshold was observed in the ears, in which the basal turn and one or more of the other turns, or the inner meatus was involved by otosclerosis.

RÉSUMÉ

Depuis 1899 quand Siebenmann a formulé sa théorie selon laquelle les métabolites qui sont produits par l'os otosclérotique, et qui exercent une influence toxique résultant en dégât de l'ouïe elle a été adoptée par un grand nombre d'auteurs. Aucune évidence microscopique a été découverte pourtant pour confirmer cette hypothèse. Les résultats des rares investigations chimiques dans lesquels le produit spécial otosclérotique a été cherché sont peut être les seules confirmant cette théorie.

Nous pourrions baser une tabulation des cas avec un foyer otosclérotique en contact avec la capsule osseuse cochléaire sur nos matériaux cliniques. Une évaluation statistique serait futile à cause de la constante présentation de matériel supplémentaire. Les trouvailles similaires d'autres investigateurs donnent l'impression qu'ils peuvent former la moitié des cas, particulièrement dans les groupes d'âge les plus avancés.

Parmi les malades les plus âgés, pas une seule instance de soi-disant burned out foyer a été observé, même plusieurs années depuis leur chirurgie. On dirait que l'envahissement autour de la capsule cochléaire a procédé d'atteindre une expansion maximum dans les âges avancés. L'intervention chirurgicale dans le voisinage de l'étrier n'a pas influencé la croissance subéquente du foyer. La transformation la plus étendue de tous les parties de la capsule otique a été évidente chez une vieille femme de 77 ans qui avait eu une difficulté auditive depuis l'âge de 18 ans, et une surdité complète depuis l'âge de 27 ans.

Une examination minutieuse de la capsule osseuse adjoint au foyer progressif n'a pas démontré aucune altération de structure dans le sens d'une pré-otosclérose. Rien n'indique une ramollissement du tils ou a l'entourage ou devant le foyer progressif. Ceci serait sans doute une des effets des métabolites produit par le foyer. Le creusement à travers les murs, osseux, fibreux, cochléaire et vestibulaire de la capsule a été accompli par force physique avec pression. Par suite ce n'était ni nécessaire ni justifiable d'accuser aucune autre force.

Aucune indication d'extension du processus otosclérotique hors de la capsule otique comme dans les grand ossicles, a été rencontré. Aucune envahissement otosclérotique de la région fissulaire a été observé. Une modification d'endost qui devait être appelé le site de prédilection a été suggéré par Helemen et Lanthier en 1906. Les soi-disant fissures congénitales de l'os temporal, qui sont rencontrés souvent, et qui ont été décrites par des autres comme le site de prédilection, n'ont pas démontré aucune relation avec le processus otosclérotique.

wie der vollständige Herd gegen den umgebenden ursprünglichen Knochen keine der beiden Komponenten konnte eine Vorzugsrolle beanspruchen, weder bezüglich Alter noch Art des Fortschreitens. Bezeichnungen wie „junge“ respektive „alte“ Herde fordern ernsthaft Revision gleichzeitig mit der ganzen, traditionell festgelegten Sequenz des metaplastischen Prozesses.

Vergleichung der ante mortem Knochenleitungsschwellen mit den histopathologischen Befunden zeigte in diesem Material, in der Mehrzahl der Individuen mit otosklerotischer Einbeziehung des kochlearen Endosteum eine Erhöhung dieser Schwelle. Dagegen zeigten nur wenige Individuen in denen die Otosklerose auf die Fußplatte oder den Vorhof beschränkt blieb, eine erhebliche Erhöhung der Knochenleitungsschwelle. Zwischen der Konfiguration des Audiogramms und der durch Otosklerose ergriffenen Partie der Schnecke bestand keine Korrelation. Doch war Erhöhung der Knochenleitungsschwelle in den Ohren zu vermerken in denen die basale Windung und eine oder mehrere der übrigen Windungen, oder der innere Gehörgang in den otosklerotischen Prozess einbezogen waren.

Tout foyer otosclérotique consiste de portions spongieux et sclérotique les deux parties constituantes étant généralement nettement divisé dans le foyer comme le foyer entier était de l'os original ni l'un ni l'autre ayant droit d'un rôle préférentiel dans le processus à cause d'âge ou d'expansion. On peut demander une révision sérieuse de termes « foyer jeune » et « foyer âgé » et de développement supposé traditionnellement, du foyer otosclérotique.

Une corrélation du seuil de la conduction osseuse *ante mortem* avec les trouvailles histopathologiques obtenu dans ces matériaux indique que la plupart des cas avec envahissement otosclérotique de l'endosteum de la cochlée avait une élévation du seuil de la conduction osseuse. Par contre chez peu de cas où l'otosclérose était limité à la base de l'étrier ou au vestibule, on a observé une élévation significative du seuil de la conduction osseuse. Il n'avait aucune relation entre la configuration de l'audiogram et les parties de la cochlée envahies par l'otosclérose. On a trouvé que le seuil de la conduction osseuse avait la tendance d'être élevé dans ces oreilles dont la courbe basale et une ou plus d'autres courbes, ou le canal auditif interne étaient envahis par le processus otosclérotique.

INTRODUCTION

T. SUZUKI

*From the Department of Otolaryngology Faculty of Medicine,
Shibashi University Niigata, Japan*

The auditory responses in experimental animals were recorded from electrodes placed directly in or on the cochlea, acoustic nerve, central auditory pathway or sensory cortex. Such direct inserting of electrodes can not be administered in man. By indirect leads, however the responses evoked by auditory stimuli are markedly attenuated by surrounding tissue, and the signals are difficult to separate from ambient noises.

This insuperable barrier of recording human evoked responses has been surmounted by the recent development of electronic computers. The averaging technique by using a computer has made it possible to identify small evoked responses which are otherwise masked with electrical background activity. The averaging technique was applied initially to the recording of the cortical evoked responses to sensory stimuli by Dawson (1954), Rémond (1956), Barlow (1957) and Geisler et al. (1958). In 1960 Lowell and associates first reported the application of a special purpose analog computer to the detection of the evoked cortical response to auditory stimulation, and in the next year they measured auditory thresholds of 54 normal adults by applying the averaged evoked response to auditory stimulus as an index of hearing. The computer used in their measurements, however integrated only the three or five gates of 2 msec width set at 20 to 50 msec after the stimulus. Consequently they did not record slow cortical evoked responses with latency of more than 50 msec.

Since the descriptions of Williams and Graham (1963) and Davis and Yoshie (1963), attention was focused on the application of the "slow" cortical evoked response, or "vertex potential" to auditory stimulus for evaluating hearing acuity. Extensive research reported since has proved that the method is a reliable and valid means of measuring hearing thresholds of infants, young children, mentally retarded individuals and noncooperative adults. The method is established and called cortical audiometry (Cody and Bickford 1965), evoked response audiometry (Davis, 1966) or computer audiometry (Theissing, 1967). Recent investigations suggest that the averaged slow cortical response can be utilized not only to the determination of hearing threshold but also to the

INTRODUCTION

T SUZUKI

*From the Department of Otolaryngology Faculty of Medicine
Shizuoka University, Matsumoto, Japan*

The auditory responses in experimental animals were recorded from electrodes placed directly in or on the cochlea acoustic nerve central auditory pathway or sensory cortex. Such direct inserting of electrodes can not be administered in man. By indirect leads, however the responses evoked by auditory stimuli are markedly attenuated by surrounding tissue, and the signals are difficult to separate from ambient noises.

This insuperable barrier of recording human evoked responses has been surmounted by the recent development of electronic computers. The averaging technique by using a computer has made it possible to identify small evoked responses which are otherwise masked with electrical background activity. The averaging technique was applied initially to the recording of the cortical evoked responses to sensory stimuli by Dawson (1954), Rémond (1956), Barlow (1957) and Geisler et al. (1958). In 1960 Lowell and associates first reported the application of a special purpose analog computer to the detection of the evoked cortical response to auditory stimulation and in the next year they measured auditory thresholds of 54 normal adults by applying the averaged evoked response to auditory stimulus as an index of hearing. The computer used in their measurements, however integrated only the three or five gates of 2 msec width set at 20 to 50 msec after the stimulus. Consequently they did not record slow cortical evoked responses with latency of more than 50 msec.

Since the descriptions of Williams and Graham (1963) and Davis and Yoshie (1963), attention was focused on the application of the "slow" cortical evoked response, or vertex potential to auditory stimulus for evaluating hearing acuity. Extensive research reported since has proved that the method is a reliable and valid means of measuring hearing thresholds of infants, young children mentally retarded individuals and noncooperative adults. The method is established and called cortical audiometry (Cody and Blackford 1963), evoked response audiometry (Davis, 1966) or computer audiometry (Thelasing, 1967). Recent investigations suggest that the averaged slow cortical response can be utilized not only to the determination of hearing threshold but also to the

diagnosis of disorders at the level of the central auditory pathway (Theissing 1967) and the objective measurement of recruitment (Cody et al 1968).

Early components of the auditory evoked response was first described by Geisler et al. (1958). Bickford et al. (1964) claimed that these components arose from muscles of the neck and their end organ receptor was the vestibular rather than the auditory apparatus. On the other hand Horwitz et al (1966) and Goldstein and Rodman (1967) stated that the early components of the evoked response to acoustic stimuli is serviceable to the determination of hearing thresholds.

Kiang and associates reported in 1963 an averaged evoked response to clicks from the human postauricular area. The authors regarded the response as an auditory myogenic response. Its application to audiometric purposes has not yet been reported.

There are a number of pioneering studies on the record of more peripheral auditory responses in man. The human cochlear microphonics was first recorded by Fromm et al (1935) with an electrode introduced through a drum perforation. The auditory nerve action potential was measured initially by Ruben et al (1960) from the round window which was surgically exposed. Lately non surgical recording of these responses were developed by Yoshie et al (1967, 1968), Portmann et al (1967, 1968), Sohmer et al (1967) and Spreng and Keidel (1967). Averaging technique was utilized for recording the responses.

The purpose of the electrophysiological measurements of human auditory responses is twofold (1) objective assessment of hearing acuity for noncooperative subjects, (2) investigation of the anatomical location and nature of auditory defects by comparing data obtained from different levels of the auditory system. Although a significant advance has been achieved within the last few years in the recording of the human auditory responses, difficulties still persist for obtaining useful diagnostic informations from the recorded responses. This monograph is devoted to our efforts to improve the recording technique of the human auditory responses and to develop the methods into useful clinical tools for diagnosing disorders of auditory function.

EVOKED RESPONSE AUDIOMETRY IN NEWBORN INFANTS*

K. TAGUCHI, T W. PICTON, J A. ORPIN and W S. GOODMAN

*From the Department of Otolaryngology, University of Toronto
(Dr Douglas P. Bryce), Toronto, Canada*

The auditory evoked responses of normal infants during natural sleep were recorded using an averaging computer. The evoked responses had two prominent components (P and N₁), which in deep sleep were of larger amplitude and of longer peak latency than in light sleep. The infants showed lower thresholds to lower frequency stimuli. The thresholds of infants less than two days old were higher than those of older infants. The peak latency of component N₁ was longer in younger infants especially in deep sleep. There was significant air bone gap in the thresholds of infants under two days old; this indicates a conductive hearing impairment in the early days after birth. Infant maturity cannot be determined precisely through study of the evoked responses because of their great variability.

The object of this study was to establish a hearing standard for normal newborn infants. This standard could then be applied to any effective newborn screening programme, and could act as a baseline in the further study of the response of the central nervous system to sound.

It has been generally agreed that there can be recorded at the vertex a long latency response to sound generated from the cortex. Usually this response is too small to be recognized in the background electrical activity of the brain. The use of the averaging computer has, however, made it possible to separate this response from the ongoing electroencephalogram. Recently many researchers (Barnet and Goodwin, 1965; Engel, 1967; Goodman et al., 1964; Graziani et al., 1968; McCandless and Best, 1964; Price and Goldstein, 1968; Rapin, 1964, 1967; Suzuki and Taguchi, 1968; Weitzman et al., 1962) have established that this method enables one to evaluate the auditory thresholds of young children and infants. They also found that evoked responses during sleep were much more easily detectable than those during the waking state because of the larger amplitude of the response and the greater ease in the handling of the subject. Fortunately almost all newborn infants will sleep after being fed and therefore can be

tested without sedation

MATERIALS AND METHODS

Subjects

Two hundred and fifty newborn infants, six hours to twelve days old were tested for air conduction auditory responses. In another series of tests to compare air conduction and bone conduction thresholds sixty infants four hours to ten days old were studied. Ten of those were retested after an interval of three days. All infants had birthweights greater than 2,500 g

Equipment

The responses were recorded in a manner similar to that previously used in our Department by Dr Shirley Appleby (Goodman et al 1964). A block diagram of the equipment is shown in Figure 1. The electroencephalogram was continuously observed as a monitor of sleep stage by means of a Beckman Type RB Dynograph. Electroencephalographic averaging over a period of 1024 msec subsequent to the sound stimulus was done on a Fabritex 1052 Signal Averager. The average evoked response was transcribed onto graph paper by a Moseley 7005 A X Y recorder.

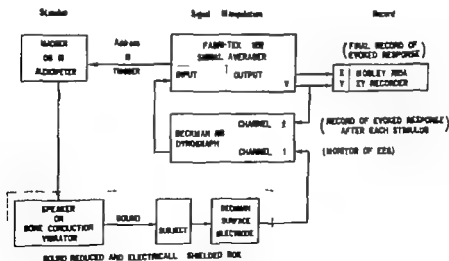

Fig. 1 Block diagram of equipment.

The sound stimulus was a short tone burst of frequencies 500 1000 or 2000 Hz from a modified Madson Electronics (Model OB 60) Audio meter. Its duration was 60 msec with a rise and decay time each of 30 msec. The free field stimulus was calibrated to ISO 1964 standard

using a Brüel and Kjaer Precision Sound Level Meter Type 2203 with an oscilloscope monitor. The bone conduction stimulus was calibrated to normal adult forehead threshold by repeated subjective testing. Thirty-two stimuli were presented at a rate of one every five seconds since preliminary experiments had indicated that this presentation gave the best results.

Procedure

The tests were performed after the 10 00 a.m. or 2 00 p.m. feeding period in a small room across the hall from the nursery. Bockman surface electrodes were applied to the vertex near the anterior fontanel (active electrode), to the right mastoid area (reference electrode) and to the left mastoid area (grounded electrode). The sleeping baby in the usual hospital bassinet, was then placed in the specially constructed sound reduced electrically shielded box. The baby could be observed at all times through the closed glass door by a nurse.

Testing was performed during light or deep sleep but not during paradoxical sleep corresponding to the REM stage of adults. Light sleep was characterized by a low voltage irregular electroencephalogram with some spindle bursts; deep sleep showed high voltage slow activity with some superimposed spindling. In the air conduction study the stimulus was first presented to the newborn at 70 dB. It was then decreased in intensity by 20 dB steps down to 10 dB. A stimulus of 10 dB less than the lowest intensity eliciting a response was also given. At the end of the test the stimulus was presented at 90 dB to obtain a definite response to aid in the interpretation of the weaker responses. The bone conduction testing was similar except that the initial stimulus was at an intensity of 50 dB.

RESULTS

Air Conduction Testing

Among the two hundred and fifty infants tested according to the described method, excellent results were obtained in 220 infants (Table 1). No infants with birth weights less than 2,500 g were tested and

TABLE 1. Ratio of successful determination of threshold to sound.

Infants—Three thresholds were obtained	220	(88.0%)
Infants—One or two thresholds were obtained	8	(3.2%)
Infants—Showed good responses to several intensities but no threshold was obtained	11	(4.4%)
Infants—No result was obtained, because of their shortness of good sleep or their movement	11	(4.4%)
Total	250	(100.0%)

tested without sedation

The figures in brackets mean the range of thresholds.

Thresholds

The threshold for evoked response audiometry was taken to be the minimal stimulus intensity which elicited a detectable cortical response (Fig. 3). The thresholds obtained listed in Table 3 and the mean threshold is plotted against age in Figure 4. The infants' threshold decreased with decreasing frequency ($P < 0.01$). Infants less than two days old showed higher thresholds than those over two days old ($p < 0.01$). Responses were considerably larger in deep sleep than in light

the minimal gestational period of these infants was 252 days (Table 2). The evoked response of the infant had two prominent components P_2 and N_2 (Figure 2). Other components seen in adult responses (P_1 , N_1 , P_3) were uncommon in sleeping infants. Statistical analysis of the results was done using an analysis of variance. Since the stage of sleep changed during the testing however statistical analysis was quite difficult. Measurements were compared only when obtained in the same stages of sleep this resulted in a considerable reduction in the amount of data available for analysis.

2-4 days	20	3.5±6.9 (0-30)	7.0±8.0 (0-30)	3.5±8.1 (10-10)
Over 4 days	20	1.5±7.5 (10-30)	4.0±8.8 (10-30)	3.0±6.6 (10-30)

The figures in the brackets mean the range of differences between air-conduction threshold and bone-conduction threshold.

decreased very significantly with decreasing intensity ($p < 0.01$). The amplitude of the response is significantly greater in deep sleep than in light sleep ($p < 0.01$) except for infants less than two days old. The response to stimuli of 70 and 90 dB in deep sleep was of smaller amplitude in infants under two days than in those over two days ($p = 0.05$).

Bone Conduction Testing

Bone conduction evoked response thresholds were obtained in 80 infants. The difference between air conduction and bone conduction thresholds were very significant within 2 days from birth ($p < 0.01$) and there was a tendency for such a gap to become insignificant after two days (Table 7). This finding was further corroborated by the fact that 10 infants examined within 2 days from birth showed a significant air bone gap ($p < 0.05$) but had no significant air bone gap when retested after an interval of 3 days (Figure 6). This suggested that young infants have a conductive hearing impairment during the first few days after birth.

DISCUSSION

This present series of tests on newborn infants began with the intention of obtaining valid estimations of normal infant auditory thresholds in order to set up an auditory screening program for newborn infants. The results obtained show that the infant's cortical evoked response to sound is affected by the stage of sleep the maturation of the infant and the presence of a conductive hearing impairment immediately after birth.

Aserinsky and Kleitman (1953), Roffwarg et al. (1964) and Wetzman et al. (1965), stated that the newborn infant has two stages of sleep

The figures in the brackets mean the number of subjects.

sleep and this seemed to result in the lower thresholds obtained during deep sleep ($p < 0.05$).

Peak Latencies

The peak latencies of P_2 and N_2 were measured (Tables 4 and 5 Figure 5). Negative trials, when responses were not identified were disregarded in calculating means. Waves P_1 , N_1 and P_3 were so often absent that no reliable means for them could be obtained. It is obvious that there was a significant difference of peak latency between light and deep sleep (P_2 $p < 0.05$ N_2 $p < 0.01$). The mean peak latency of component N_2 was longer in younger infants especially during deep sleep ($p < 0.01$), but there was no significant differences in the mean peak latencies of P_2 of the three age groups ($p > 0.05$). There were no differences in latency among the three frequencies ($p > 0.05$) except for P_2 at 70 dB ($p < 0.01$). It is noteworthy that with an increase in intensity of stimulus there was a decrease in the latencies of both components P_2 and N_2 ($p < 0.01$).

Amplitude

The peak to peak amplitude ($\overline{P_2N_2}$) of the evoked response was measured at the intensities of 50, 70 and 90 dB (Table 6). Amplitude

TABLE 7 Difference between air conduction threshold and bone conduction threshold in deep sleep Mean and standard deviation (dB).

Age group	Number of subjects	Stimulus frequency (Hz)		
		500	1000	2000
0-3 day	20	17.0±12.0 (0-40)	22.5±13.0 (0-40)	11.0±9.8 (0-40)
2-4 day	20	5.5±6.9 (0-20)	7.0±8.0 (0-30)	3.5±6.1 (0-10)
Over 4 day	20	1.5±7.5 (-10-20)	4.0±8.8 (-10-30)	3.0±6.6 (-10-20)

decreased very significantly with decreasing intensity ($p < 0.01$). The amplitude of the response is significantly greater in deep sleep than in light sleep ($p < 0.01$) except for infants less than two days old. The response to stimuli of 70 and 90 dB in deep sleep was of smaller amplitude in infants under two days than in those over two days ($p < 0.05$).

Bone Conduction Testing

Bone conduction evoked response thresholds were obtained in 60 infants. The difference between air conduction and bone conduction thresholds were very significant within 2 days from birth ($p < 0.01$) and there was a tendency for such a gap to become insignificant after two days (Table 7). This finding was further corroborated by the fact that 10 infants examined within 2 days from birth showed a significant air bone gap ($p < 0.05$) but had no significant air bone gap when retested after an interval of 3 days (Figure 6). This suggested that young infants have a conductive hearing impairment during the first few days after birth.

DISCUSSION

This present series of tests on newborn infants began with the intention of obtaining valid estimations of normal infant auditory thresholds in order to set up an auditory screening program for newborn infants. The results obtained show that the infant's cortical evoked response to sound is affected by the stage of sleep, the maturation of the infant and the presence of a conductive hearing impairment immediately after birth.

Aserinsky and Kleitman (1953), Hoffmann et al. (1964) and Weitzman et al. (1965) stated that the newborn infant has two stages of sleep

Fig. 8. Comparison of air-conduction threshold with bone conduction threshold. Means of ten subjects.

a quiescent and an active phase. Quiescent sleep shows high voltage slow wave EEG activity and active sleep has a characteristic low voltage fast EEG activity. In adults there are significant changes in amplitude and latency of the evoked response components during different sleep stages (Weltzman and Kremen 1965, Williams et al 1962 and 1964). In infants the changes seem to be basically the same as in adults (Suzuki and Taguchi 1968, Weltzman et al 1965). Our present results agree with these reports, except that we found no difference in P_2 peak latency between age groups. Barnett and Goodwin (1965) stated that larger amplitudes and longer latencies were often associated with deeper sleep, but this effect was less in infants than in adults. Our present study showed that there was no difference in response amplitude between light and deep sleep in our youngest age group although there was a significant difference in the older infants. We think that such a finding suggests the further development of the sleep stages after birth.

Infant maturational changes must be considered in this kind of testing. This study showed a decrease in N_2 latency as a function of age. Barnett (1965) reported that the evoked response latency to sound (P_2) seemed to remain constant or to increase slightly for about six weeks after birth and then to decline. Engol (1967) stated that the

mean peak latency of P_2 was longer in younger infants than in older children or adults.

Our present study of bone-conduction thresholds suggests that the high air conduction thresholds obtained in younger infants are caused by an incomplete conductive mechanism. This is a new finding. The middle ear is fully formed by the last month of fetal life (Bast and Anson 1949; Eggston and Wolff 1947), but some mesenchymal tissue remains in the tympanic cavity right after birth (Igarashi, 1968) which could account for a conductive hearing impairment.

An evoked response screening test can be performed by presenting 70 dB tone bursts of 500, 1000 and 2000 Hz frequencies to an infant 2 to 4 days old during deep sleep. If the infant has normal hearing there will be an easily recognizable response to 32 stimuli presented at a rate of one every 5 seconds. We have so far successfully screened 100 infants by this procedure.

Our present overall screening programme involves several steps. The infant is initially tested for behavioural responses to warble tones by trained volunteers. If the response is questionable the infant is retested by an audiologist. If again no response is obtained the infant undergoes the evoked response screening test previously described. Questionable results on this test will entail complete evoked response audiometry and intensive further medical evaluation of the child.

Using cortical evoked responses we have established the auditory thresholds of normal infants. We believe that evoked response audiometry has a very significant part to play in any newborn auditory screening programme.

ZUSAMMENFASSUNG

Die vorliegende Untersuchung wurde durchgeführt, um einen Maassstab für die Beurteilung des normalen Neugeborenengehörs zu erhalten, der für Reiben unter suchungen erwandt werden kann. Die auditorisch hervorgerufenen Reaktionen ("evoked responses") des sich in natürlichem Schlaf befindenden Säuglings wurden unter Benutzung eines Computers registriert. Als Stimuli wurden in einem Abstand von je 5 Sekunden Schallstöße ("tone bursts") von je 500, 1000 und 2000 Hz Frequenz angewandt. Jede Gesamtreaktion setzte sich aus 32 Einzelreaktionen zusammen. Die Reaktionen des schlafenden Kleinstkindes hatten zwei bemerkenswerte Komponenten P_1 und P_2 . Ungewöhnlich dagegen waren die beim Erwachen eintreffenden Komponenten P_1 und P_2 . Die zwei Hauptkomponenten der hervorgerufenen Reaktionen waren in tiefem Schlaf grösser als in oberflächlichem

Fig. 6. Comparison of air conduction threshold with bone conduction threshold. Means of ten subjects.

a quiescent and an active phase. Quiescent sleep shows high voltage, slow wave EEG activity and active sleep has a characteristic low voltage fast EEG activity. In adults there are significant changes in amplitude and latency of the evoked response components during different sleep stages (Woltzman and Kremon 1965, Williams et al 1962 and 1964). In infants the changes seem to be basically the same as in adults (Suzuki and Taguchi 1968, Woltzman et al 1965). Our present results agree with these reports, except that we found no difference in P_2 peak latency between age groups. Barnett and Goodwin (1965) stated that larger amplitudes and longer latencies were often associated with deeper sleep but this effect was less in infants than in adults. Our present study showed that there was no difference in response amplitude between light and deep sleep in our youngest age group although there was a significant difference in the older infants. We think that such a finding suggests the further development of the sleep stages after birth.

Infant maturational changes must be considered in this kind of testing. This study showed a decrease in N latency as a function of age. Barnett (1965) reported that the evoked response latency to sound (P_2) seemed to remain constant or to increase slightly for about six weeks after birth and then to decline. Engel (1967) stated that the

und zeigten längere Spitzenlatenzen. Die Säuglinge hatten bei niedrigen Frequenzen einen besseren Schwellenwert. Neugeborene, die jünger als zwei Tage alt waren, zeigten im Vergleich mit Älteren eine schlechtere Schwelle. Bei jüngeren Neugeborenen besonders im tiefen Schlaf war die mittlere Spitzenlatenz zur Komponente N₂ länger. Außerdem wurden in der Amplitude der Reaktionen während tiefen Schlafens signifikante Differenzen zwischen der Altersgruppe unter 2 Tagen und der über 2 Tagen gefunden. Ein signifikanter Unterschied der Luftleitungs- und Knochenleitungsschwelle wurde in der Altersgruppe unter 2 Tagen festgestellt. Es ist anzunehmen, dass in den ersten Tagen nach der Geburt eine konduktive Schwerhörigkeit vorliegt. Die Individualität der hervorgerufenen Reaktionen kann so variabel sein, dass die Maturität des Prüflings durch obige Untersuchungen nicht präzise festgelegt werden kann.

AVERAGED EVOKED RESPONSE AUDIOMETRY (ERA) IN YOUNG CHILDREN DURING SLEEP

T. SUZUKI and K. ORIGUCHI

*From the Department of Otolaryngology Faculty of Medicine
Shinshu University Matsumoto Japan*

Thresholds of averaged evoked response to auditory stimulation for sleeping young children were compared with thresholds obtained from conditioned orientation reflex (COR) audiometry. Forty seven normally hearing children aged 4 months through 4 years and 133 hard-of-hearing children aged between 1 and 5 years were tested. Of these, data from 42 normal and 88 hearing impaired children were available for the comparison. The evoked response was recorded using tone bursts of 500, 1000, 2000 and 4000 Hz. They had 25 msec rise and fall time and 100 msec duration and were delivered every 5 sec. Approximately 30 responses were averaged during test run. The test was administered in sleep stages 3 and 4 of the classification of Dement and Kleitman. COR audiometry was made according to the original method of Suzuki and Ogiba.

For normal children the mean difference between both thresholds was 12.38 dB, COR threshold more sensitive, and 98.2 per cent of measurements fell within the range between 0 and 20 dB. For slightly or moderately impaired children the mean difference decreased to 6.38 dB, COR thresholds more sensitive. For severely impaired subjects the mean difference was only 0.43 dB, evoked response more sensitive. Significantly smaller difference between evoked response threshold and COR threshold was proved statistically in hard-of-hearing children than in normal children.

The literature is growing rapidly with reports on the use of averaged evoked response to acoustic stimuli for assessing hearing acuity of young children and noncooperative adults. The term "evoked response audiometry (ERA)" is now widely accepted for this technique. For validating the audiometric application of the evoked response some investigators compared the evoked response threshold with voluntary or behavioral audiometric threshold in adults (Cody et al. 1965; Davis, 1966; McCandless et al. 1966, 1968; Suzuki et al. 1965) and in children (Davis, 1965, 1966; Davis et al. 1967; McCandless, 1967; Price et al. 1968), most of them indicating an excellent approximation of both thresholds. However, few reports have been published on the validation of ERA in young children where this technique is needed most. It is of course due mainly to the lack of reliable methods for determining accurate hearing acuity of young children.

AVERAGED EVOKED RESPONSE AUDIOMETRY (ERA) IN YOUNG CHILDREN DURING SLEEP

T. SUZUKI and K. ORIGUCHI

*From the Department of Otolaryngology Faculty of Medicine
Shizuoka University Matsumoto Japan*

Thresholds of averaged evoked response to auditory stimulation for sleeping young children were compared with thresholds obtained from conditioned orientation reflex (COR) audiometry. Forty seven normally hearing children aged 4 months through 4 years and 133 hard-of-hearing children aged between 1 and 5 years were tested. Of these, data from 42 normal and 92 hearing impaired children were available for the comparison. The evoked response was recorded using tone bursts of 500, 1000, 2000 and 4000 Hz. They had a 25 msec rise and fall time and 100 msec duration and were delivered every 8 sec. Approximately 30 responses were averaged during a test run. The test was administered in sleep stages 3 and 4 of the classification of Dement and Kleitman. COR audiometry was made according to the original method of Suzuki and Ogiba.

For normal children the mean difference between both thresholds was 10.38 dB, COR threshold more sensitive, and 96.2 per cent of measurements fell within the range between 0 and 20 dB. For slightly or moderately impaired children the mean difference decreased to 6.38 dB, COR thresholds more sensitive. For severely impaired subjects the mean difference was only 2.43 dB, evoked response more sensitive. Significantly smaller difference between evoked response threshold and COR threshold was proved statistically in hard-of-hearing children than in normal children.

The literature is growing rapidly with reports on the use of averaged evoked response to acoustic stimuli for assessing hearing acuity of young children and noncooperative adults. The term "evoked response audiometry (ERA)" is now widely accepted for this technique. For validating the audiometric application of the evoked response, some investigators compared the evoked response threshold with voluntary or behavioral audiometric threshold in adults (Cody et al. 1965; Davis, 1966; McCandless et al. 1966, 1968; Suzuki et al. 1965) and in children (Davis, 1965, 1966; Davis et al. 1967; McCandless, 1967; Price et al. 1966), most of them indicating an excellent approximation of both thresholds. However, few reports have been published on the validation of ERA in young children where this technique is needed most. It is of course due mainly to the lack of reliable methods for determining accurate hearing acuity of young children.

Fig 1 Blockdiagram of equipment.

The present paper deals with results of evoked response audiometry during sleep in comparison with those obtained from behavioral technique using conditioned orientation reflex (COR) audiometry for young children under five years of age.

METHOD

Subjects

The study comprised 47 normally hearing children aged 4 months through 4 years and 133 hard of hearing children between 1 and 5 years of age. The normal subjects were presumed to have normal hearing in both ears by their histories and otoscopic findings. All of the hard of hearing subjects came from the Speech and Hearing Clinic of the Department of Otolaryngology of Shinshu University. Their mental development was tested previously by using nonverbal techniques and proved to have intelligence quotients not worse than 85.

Equipment

The equipment used for recording the evoked response is shown by the block diagram in Fig 1. Tone bursts at frequencies 500, 1000, 2000 and 4000 Hz were used as stimuli. They had a 25 msec rise and fall time and a 100 msec duration. The tones were led to one of the subjects' ears by earphones (Iwasaki AH 801) at intervals of 5 sec. The reference levels of the test tones were calibrated by 10 normally hearing young adults. Each series of responses was averaged by means of an analog type computer (San Ei AR 201) and the averaged responses were read out on an oscilloscope (Iwasaki SS 5022). Original EEG pattern was recorded on an ink writing recorder for determining subject's sleep stage. In the majority of cases 30 responses were averaged during a test run.

Fig. 2. Typical pattern of averaged evoked response from 3-year-old girl to 30 presentations of 1000 Hz tone at 30 dB above her subjective threshold during sleep stage 3. Upward deflection indicates negativity to active electrode.

Procedures

The subjects were sedated with an intramuscular injection of 3 mg per kg of pentobarbital sodium and laid on a bed in a sound proof room. Following onset of sleep, active electrode was fixed at the vertex (Cz), reference electrode at the right mastoid area and ground electrode at the forehead.

The tone stimulus was first given at an intensity above estimated threshold level of the ear under test. If a clear response was recorded the intensity was reduced by 10 dB steps until the response was no longer visualized. Since the most prominent evoked response to auditory stimulus was obtained in sleep stages 3 and 4 of the classification by Dement and Kleitman (1957) (Suzuki et al. 1968; Weitzman et al. 1963), the recording was made in these stages.

Criteria of the Response

The presence or absence of the evoked response was determined by two or three examiners from the pattern on the oscilloscope. Following criteria were adopted for determining the positive response in sleep stages 3 and 4.

1. The response was judged as positive when its three main components, i. e. N_1 (first negative deflection) with peak latency of 110 to 160 msec, P_1 of 20 to 300 msec and N_2 of 380 to 550 msec or at least P_1 and N_2 appeared and grew with repetition of the stimulus (Fig. 2).

2. When a response was questionable at a given intensity level, its pattern was compared with that of positive response at 10 dB higher level of stimulation. When a close similarity was found between both patterns, the response was judged as positive (Fig. 3). It should be kept in mind that the peak latencies in the response tend to increase

Fig. 3. Averaged evoked response in a girl aged 15 months to 20 presentations of a 1000 Hz tone. The response is questionable at 70 dB SL (A). However by comparing its pattern with that of clear positive response at 80 dB SL (B), the response in 70 dB can be judged as positive.

as stimulating level decreases.

Conditioned Orientation Reflex (COR) Audiometry

COR audiometry is a behavioral testing technique with which pure tone thresholds for young children under three years of age can be measured. Visual orientation reflex is conditioned with pure tones and utilized as index of hearing. For the present study the original method of Suzuki and Ogiba (1961) was used and the hearing thresholds for four frequencies of 500 1000 2000 and 4000 Hz were measured in 10 dB steps by a descending technique.

Comparison of ERA and COR

All of the subjects had been tested by COR audiometry prior to being tested by ERA. At the time of performing ERA the examiners were unaware of the results of COR test. Since COR test was made in free field binaurally evoked response threshold of the better ear was compared with COR threshold of the same frequency.

RESULTS

Normal Subjects

In 5 of the 47 normal children ERA was unsuccessful chiefly because of the failure in maintenance of adequate sleep stages. Table 1 shows the distribution of thresholds by ERA and COR audiometry in the

TABLE 1. *Distribution of evoked response (ER) and COR thresholds for normal children.*

remaining 4. children aged 4 months through 4 years. Since no significant difference in the thresholds was found as a function of the frequency of stimulating tones, the data obtained in four frequencies were summed up and presented collectively in a table.

Fig. 4 indicates the variation of mean values of both thresholds as a function of subjects age. Noteworthy is the fact that evoked response thresholds tend to decrease in parallel with COR thresholds as the child becomes older showing the averaged difference of about 10 dB in each age category.

Table 2 presents the distribution of the difference between evoked response thresholds and COR thresholds. Comparison was made in 131

Fig. 3. Averaged evoked response in a girl aged 15 months to 20 presentations of a 1000 Hz tone. The response is questionable at 70 dB SL (A). However by comparing its pattern with that of clear positive response at 80 dB SL (B), the response in 70 dB can be judged as positive.

as stimulating level decreases.

Conditioned Orientation Reflex (COR) Audiometry

COR audiometry is a behavioral testing technique with which pure tone thresholds for young children under three years of age can be measured. Visual orientation reflex is conditioned with pure tones and utilized as index of hearing. For the present study the original method of Suzuki and Ogiba (1961) was used and the hearing thresholds for four frequencies of 500 1000 2000 and 4000 Hz were measured in 10 dB steps by a descending technique.

Comparison of ERA and COR

All of the subjects had been tested by COR audiometry prior to being tested by ERA. At the time of performing ERA the examiners were unaware of the results of COR test. Since COR test was made in free field binaurally evoked response threshold of the better ear was compared with COR threshold of the same frequency.

RESULTS

Normal Subjects

In 5 of the 47 normal children ERA was unsuccessful chiefly because of the failure in maintenance of adequate sleep stages. Table 1 shows the distribution of thresholds by ERA and COR audiometry in the

than evoked response thresholds in normal subjects comes less prominent in group 1 and completely disappears in group 2. The mean difference for group 1 is 6.38 dB COR threshold more sensitive, whereas for group 2 it is only 0.43 dB evoked response threshold more sensitive. Statistical investigation of these data including those of normal subjects, revealed that the difference between COR threshold and evoked response threshold diminishes significantly as degree of hearing losses increases.

COMMENT

Early investigators (Suzuki et al. 1962 Appleby et al. 1963 Davis, 1964 McCandless et al. 1964) obtained cerebral evoked response, or vertex potential, with auditory stimulation at 10 dB to 25 dB SL in normal adults. Validating study made by us (Suzuki et al. 1965) showed that the detectable response was obtained in 70 per cent of normal adults with stimulus intensity at 10 dB SL and in 100 per cent at 20 dB SL. McCandless and Best (1966) indicated that the response was seen quite clearly at 10 dB SL in 8 of 10 subjects. Davis (1966) reported the approximate difference between evoked response threshold and behavioral threshold for normal adults ranging from 7.5 to 12.5 dB behavioral more sensitive. McCandless and Lontz (1969) reported that the evoked response measured from 12 normal adults agreed within 8 dB of their voluntary threshold. Price and Goldstein (1968) compared evoked response threshold and behavioral threshold for 7 normal children. However no numerical evaluation was presented in their paper.

In the present study the evoked response threshold for normal children was proved to be approximately 10 dB higher than the behavioral threshold for each age category of 1 to 4 years. The results obtained here correspond closely with those in most of the previous reports for normal adults in spite of the difference in the testing technique for the behavioral audiometry. It is of interest that the evoked response thresholds for normal young children decrease successively in

pairs of thresholds obtained from 42 children. Again in this comparison the data obtained in four frequencies were combined in a table. The overall distribution of the difference in normal children is almost symmetrical and all but 6 measurements fall within the range between 0 and 20 dB COR threshold more sensitive. The mode is 10 dB and the mean value is 10.38 dB

Clinical Subjects

ERA could not be administered successfully in 11 of 133 hard of hearing children because of failures in the testing procedure. Another 30 severely impaired children showed no response in either ERA or COR audiometry or in both of them even at the maximum intensity level of the stimulating tones. The remaining 92 children aged 1 through 5 years gave a total of 315 pairs of thresholds, which were divided into two groups according to the threshold values for COR test. Group 1 consisted of 130 measurements whose COR thresholds ranged between 20 and 60 dB average value being 49.0 dB. Group 2 comprised 185 measurements from severely impaired ears with COR thresholds of 70 dB or higher and of 82.9 dB as average.

Table 3 and 4 show the distribution of difference between both thresholds for the above mentioned two clinical groups. As is presented in the tables the trend toward higher sensitivity of COR thresholds

pairs of thresholds obtained from 42 children. Again in this comparison the data obtained in four frequencies were combined in a table. The overall distribution of the difference in normal children is almost symmetrical and all but 6 measurements fall within the range between 0 and 20 dB COR threshold more sensitive. The mode is 10 dB and the mean value is 10.38 dB.

Clinical Subjects

ERA could not be administered successfully in 11 of 133 hard of hearing children because of failures in the testing procedure. Another 30 severely impaired children showed no response in either ERA or COR audiometry or in both of them even at the maximum intensity level of the stimulating tones. The remaining 92 children aged 1 through 5 years gave a total of 315 pairs of thresholds, which were divided into two groups according to the threshold values for COR test. Group 1 consisted of 130 measurements whose COR thresholds ranged between 20 and 60 dB average value being 49.0 dB. Group 2 comprised 185 measurements from severely impaired ears with COR thresholds of 70 dB or higher and of 82.9 dB as average.

Table 3 and 4 show the distribution of difference between both thresholds for the above mentioned two clinical groups. As is presented in the tables the trend toward higher sensitivity of COR thresholds

30 Mittelungen. Gemäss der Klassifizierung von Dement und Kleitman wurde die Prüfung im Schlafstadium 3 und 4 durchgeführt. Beim Orientierungsreflex Verfahren wurde der Originalmethode von Suzuki und Ogiba gefolgt.

Bei normalen Kindern erreichte der mittlere U Unterschied zwischen den beiden Schwellen 10.35 dB, dabei war die Empfindlichkeit der "COR" Schwelle grösser und 90.4 Prozent der Messungen bewegten sich im Bereiche von 11 bis 20 dB. Bei Kindern mit einer geringgradigen oder mittelgradigen Schwerhörigkeit nahm der mittlere Unterschied bis zu 6.38 dB ab, dabei war die Empfindlichkeit der "COR" Schwelle grösser. Bei den hochgradigschwerhörigen Untersuchten betrug der mittlere U Unterschied nur 0.43 dB, wobei aber die evokierten Erregungsantworten empfindlicher waren. Ein signifikant kleinerer U Unterschied zwischen der durch das Mittelungsverfahren bestimmten Schwelle evokierter Erregungsantworten und der "COR" Schwelle wurde eher bei schwerhörigen Kindern als bei normalhörenden Kindern statistisch erwiesen.

parallel with the behavioral thresholds as the subjects age increases.

For hard of hearing children the relation between evoked response threshold and behavioral threshold is quite different from that for normal subjects. Rapin (1964) compared evoked response threshold and subjective threshold on 36 children with hearing losses of 50 dB or higher and one child of normal hearing. In 19 of 37 children the two thresholds were within 10 dB of each other. In 23 of 37 instances the evoked response was more sensitive than the subjective threshold.

Davis and associates (1965, 1966, 1967) also made such a comparison in 162 hard of hearing children aged 4 through 15 years. The average difference was only 0.9 dB, subjective response more sensitive. In 119 of the 162 cases the difference fell within 7.5 dB. Other reports (McCandless, 1967; McCandless et al., 1968; Thoising, 1967) indicated almost the same results.

Our present findings in hearing impaired children aged 1 to 5 years correspond closely to the above mentioned data and confirmed that significantly closer approximation of the evoked response threshold to the behavioral threshold occurred in subjects with hearing impairments than in normal subjects. The cause of this discrepancy between normal and impaired subjects is not clear. Rapid development of loudness in the ear with sensori neural defects may play a causal part in this discrepancy.

Though there is no theoretical necessity for exact agreement between evoked response threshold and voluntary threshold, it is practically of great convenience for estimating the hearing acuity of young children with evoked response audiometry.

ZUSAMMENFASSUNG

Die durch das Mittelungsverfahren bestimmten Schwellen evokierter Erregungsantworten auf akustische Reize bei schlafenden kleinen Kindern wurden mit den durch das Verfahren der konditionierten Orientierungsreflexe ("COR, conditioned orientation reflex") ermittelten Schwellen verglichen. 47 normalhörende Kinder im Alter zwischen 4 Monaten und 4 Jahren sowie 133 schwerhörige Kinder im Alter zwischen 1 und 5 Jahren wurden geprüft. Davon waren die Prüfungsergebnisse von 42 normalhörenden und diejenigen von 92 schwerhörigen Kindern zum Vergleich zugänglich. Die Registrierung der evokierten Erregungsantworten erfolgte bei Verwendung von Sinustonimpulsen, deren Frequenz 500, 1000, 2000 und 4000 Hz betrug. Diese 100 ms dauernden Sinustonimpulse hatten eine An- und Abklingzeit von 25 ms und wurden alle 5 Sekunden dargeboten. Im Verlauf einer Untersuchungsserie beruhte die Identifizierung der evokierten Potentiale auf ungefähr

HUMAN FETAL EVOKED RESPONSE TO ACOUSTIC STIMULATION

N. SAKABE, T. ARAYAMA and T. SUZUKI

*From the Department of Otolaryngology, Faculty of Medicine,
Shinshu University Matsumoto Japan*

Human fetal evoked response to acoustic stimuli was recorded from the abdominal wall of six mothers at the 32th to 38th week of pregnancy. Tone bursts with frequency of 1000 Hz, duration of 30 msec, and rise and decay time of 13 msec were given every 4 seconds through a bone vibrator attached to the maternal abdominal wall at the nearest place to the fetal ear. The responses were conducted through an active electrode located on the maternal abdominal wall in the vicinity of the fetal vertex and were averaged by digital computer.

The typical wave form of the response consisted of four prominent deflections: negative, a positive, negative and positive deflection with respective peak latencies of 100 to 150 msec, 200 to 300 msec, 500 to 600 msec and 700 to 800 msec. These deflections of the fetal evoked response were considered to correspond to the four components (N_1 , P_1 , N_2 , P_2) of the slow "vertex potential" to auditory stimulus in young children. However, the decision can not be reached as to whether the response obtained in the present study is originated in the fetal brain and depends on the fetal auditory function.

Recently the cerebral evoked responses to acoustic stimuli in newborn infants and young children can be detected easily by averaging the responses using electronic computers. The method has already been well established and applied to audiometric purposes. However little has been written on the cerebral evoked responses to acoustic stimulation in fetuses and no attempt has been reported on the fetal evoked response recorded with electrodes attached to the abdominal wall of a pregnant woman. The present paper is a preliminary report of our study on the recording of the fetal evoked response to tonal stimulation by the abdominal leads with the hope of developing a method for detecting hearing defects of a child during its fetal life.

HUMAN FETAL EVOKED RESPONSE TO ACOUSTIC STIMULATION

N. SAKABE, T. ARAYAMA and T. SUZUKI

*From the Department of Otolaryngology, Faculty of Medicine,
Shinshu University, Matsumoto, Japan*

Human fetal evoked response to acoustic stimuli was recorded from the abdominal wall of six mothers at the 32th to 38th week of pregnancy. Tone bursts with frequency of 1000 Hz, duration of 50 msec, and rise and decay time of 13 msec were given every 4 seconds through a bone vibrator attached to the maternal abdominal wall at the nearest place to the fetal ear. The responses were conducted through an active electrode located on the maternal abdominal wall in the vicinity of the fetal vertex and were averaged by a digital computer.

The typical wave form of the response consisted of four prominent deflections: a negative, a positive, a negative and a positive deflection with respective peak latencies of 100 to 150 msec, 200 to 300 msec, 500 to 600 msec and 700 to 800 msec. These deflections of the fetal evoked response were considered to correspond to the four components (N_1 , P_1 , N_2 , P_2) of the slow vertex potential to auditory stimulus in young children. However, the decision can not be reached as to whether the response obtained in the present study is originated in the fetal brain and depends on the fetal auditory function.

Recently the cerebral evoked responses to acoustic stimuli in newborn infants and young children can be detected easily by averaging the responses using electronic computers. The method has already been well established and applied to audiometric purposes. However little has been written on the cerebral evoked responses to acoustic stimulation in fetuses and no attempt has been reported on the fetal evoked response recorded with electrodes attached to the abdominal wall of a pregnant woman. The present paper is a preliminary report of our study on the recording of the fetal evoked response to tonal stimulation by the abdominal leads with the hope of developing a method for detecting hearing defects of a child during its fetal life.

METHOD

Subjects

Six healthy mothers at the 32th to 38th week of normal pregnancy were selected for the investigation. Their fetal heads were located on

Fig. 1 Block diagram of equipment.

Fig. 2 Interval duration and rise and decay time of stimulating tone

the pelvis of the mothers and protruded in the lower part of the hypogastric region.

Equipment and procedure

The block diagram of the equipment used for the present study is shown in Fig. 1. The acoustic stimulus used was a tone burst with frequency of 1000 Hz, duration of 50 msec and rise and decay time of 13 msec (Fig. 2). The stimulus was given every 4 seconds through a bone conduction vibrator (Rion BCR 4) fixed closely to the skin of the maternal abdomen at the nearest place to the fetal ear (Fig. 3). The vibration amplitude of the vibrator was calibrated with an accelerometer and fixed at 50 microns throughout the present investigation. However, the actual intensity of the stimulating tone which is delivered to the fetal ear could not be measured.

Electrodes were placed on the median line of the abdominal wall of the mothers. As shown in Fig. 3, an active electrode was fixed at the nearest place to the fetal vertex while a reference electrode was attached to the fetal cervical region.

Original waves were examined previously with an oscilloscope so as to avoid the mixture of maternal ECG and artifacts. Original res-

Fig 3. Schematic representation of position of electrodes and bone conduction vibrator.

ponses and signals of the stimulus were recorded separately on two channels of a data recorder (San'El AR 201) and a subsequent averaging was carried out by means of a digital computer (San'El MC 401). Averaging number ranged from 80 to 100.

As a rule the maternal ears were masked with a white noise of sufficient intensity during the examination.

RESULTS

Averaged evoked responses of a characteristic wave form were obtained using electrodes placed on the maternal abdominal wall. As shown in Fig. 4 and 5, typical wave form of the evoked response consists of four successive deflections. The initial negative deflection (N_1) is seen at approximately 100 to 150 msec from the onset of the stimulating tone. Next positive deflection (P_1) at 200 to 300 msec is followed by a negative deflection (N_2) at 500 to 600 msec and a later positive deflection (P_2) with peak latency of 700 to 800 msec. Not all peaks were clearly obtained in all responses. Noted is that P_2 and N_2 were recognized in all subjects examined while N_1 and P_1 were equivocal or absent in some cases. Of course such time locked deflections could not be observed in records obtained from the maternal abdominal wall when no acoustic stimulation was presented (Fig. 6).

Fig. 7 indicated a comparative observation on the averaged evoked response to auditory stimulation in a newborn baby who was born prematurely at the 5th day of the 37th week of pregnancy. The response

Fig. 4. A typical evoked response to acoustic stimulus recorded from a maternal abdominal wall at the 36th week of pregnancy. Four successive deflections are observed. Stimulus: 1000 Hz tone burst. Vibration amplitude: 50 μ . Averaging number: 50.

Fig. 5. Evoked response to acoustic stimulus recorded from another maternal abdominal wall at the 36th week of pregnancy. The component P is equivocal. Stimulus: 1000 Hz tone burst. Vibration amplitude: 50 μ . Averaging number: 50.

Fig. 6. Averaged wave from the same subject when the acoustic stimulus is not given.

Fig. 7. Averaged evoked response to acoustic stimulus recorded from the vertex of newborn baby who was born prematurely at the 6th day of the 37th week of pregnancy. Components P, N and P are clearly observed.

Stimulus: 1000 Hz tone burst. Intensity: 85 dB SPL. Averaging number: 30.

Fig. 8. Averaged wave from the abdominal wall of a non-pregnant woman. Tone stimulus was 1000 Hz in the same way as shown in Fig. 4 and 5.

was recorded 8 hours after birth from the vertex of the baby's scalp with stimulating tone of 1000 Hz at the intensity level of 85 dB SPL given through a speaker placed at 20 cm from the baby's head. A close similarity was found in the patterns between the fetal evoked response and that in the newborn baby.

Fig. 8 shows an averaged wave recorded from the abdominal wall of a normal non-pregnant woman to whom the acoustic stimulation was given in quite the same way as it was given to the pregnant subjects. The wave was flat and no evoked response was detectable. The initial deflections in the wave were an artifact due probably to a leakage of the stimulating tone.

COMMENT

The fetal reactivity to acoustic stimulation was first reported by Peiper in 1924. He observed changes in the fetal movement in response to intense sound stimulation in a fetus of 40 weeks of age. Recent investigations indicated that the fetus in the third trimester of intrauterine life reacted to acoustic stimuli by changes in the fetal movement and heart rate (Bernard et al. 1947, Fleischer 1955, Murphy et al. 1962, Johanson et al. 1964, Dwornicka et al. 1964, Smyth et al. 1967).

Lindsley (1949) recorded the fetal brain potential in a fetus of 7 months of age with electrodes placed on the maternal abdominal wall. Okamoto and Kirikae (1951) observed the electrical activity of the fetal brain as early as 8 weeks of age. More recently several investigators recorded the fetal EEG using scalp, vaginal or abdominal electrodes and endorsed the existence of the electrical activity in the human fetal brain (Bernstine et al. 1955, Borkowski et al. 1955, Rosen et al. 1965).

Hon et al. (1967) recorded the fetal evoked response to acoustic stimuli with the purpose of investigating the fetal physiological state during delivery by comparing the changes in the evoked response with those in the heart rate. They attached two electrodes to the fetal vertex which entered into the birth canal during labor and presented acoustic stimuli to the fetus by inserting an earphone near one of the fetal ears. Averaging technique was utilized for recording the evoked response. The authors claimed that there are definite wave forms which bear a temporal relationship to the stimulus. When the fetus was in normal status typical triphasic patterns of the auditory evoked response were observed. Barden et al. (1968) also attempted to record the fetal auditory evoked response with fetal scalp electrodes. They obtained the evoked response in one of six subjects. The response appeared to be similar in wave form to the auditory evoked response in newborn babies.

All the above mentioned studies imply us a strong possibility of the existence of the auditory evoked response in the fetal brain which corresponds to that obtained from the vertex of newborn babies. The present study revealed that an averaged evoked response to acoustic stimuli could be recorded with electrodes placed on the abdominal wall of pregnant mothers. Four successive deflections observed in the fetal evoked response appeared to correspond closely to the four components (N_1 , P , N_2 , P_2) of the averaged evoked response, or "vertex potential" to auditory stimulation in newborn children (Goodman et al. 1964, Woltzman et al. 1965). The response did not appear without

tonal stimulation, nor was it obtained unless the active electrode was placed in close proximity to the fetal vertex even though the stimulus was given. It could not be recorded from the abdominal wall of non pregnant woman.

From the method used in the present study and the results obtained, there can be little doubt that the response obtained is a fetal response. However problems still remain with reference to the nature of the response and it is impossible at the present time to decide whether the response is elicited from the fetal brain with the stimulus conducted through the cochlea. The study will be further extended to improve testing technique and to investigate the clinical value of the response.

ACKNOWLEDGMENT

The authors wish to extend their thanks to Dr J A. Orpin for the careful review of the manuscript and to Dr E. König for German translation.

ZUSAMMENFASSUNG

Evokierte Erregungsantworten auf akustische Reize beim menschlichen Fetus wurden bei 6 Müttern an der abdominalen Wand im Zeitpunkt zwischen der 32. und der 38. Woche der Schwangerschaft registriert. Stimulusimpulse mit einer Frequenz von 1000 Hz, einer Dauer von 50 ms und einer An- und Abklingzeit von je 13 ms wurden alle 4 Sekunden durch einen an der mütterlichen abdominalen Wand möglichst nahe beim Ohr des Fetus fixierten Knochenvibrator dargeboten. Die evokierten Erregungsantworten wurden über eine sich an der mütterlichen abdominalen Wand in der Nähe des Scheitels des Fetus befindliche aktive Elektrode geleitet und mit Hilfe eines Digital Computers gemittelt.

Der typische Wellenverlauf der evokierten Erregungsantworten bestand aus vier ausgeprägten Auslenkungen: einer negativen, einer positiven, einer negativen und einer positiven Auslenkung mit Spitzenlatenzen von 100 bis 150 ms, 200 bis 300 ms, bzw. von 500 bis 600 ms und 700 bis 800 ms. Diese Auslenkungen der evokierten Erregungsantworten des Fetus betrachtet man als den vier Komponenten (N_1 , P_1 , N_2 , P_2) des evokierten langsamen "verrier Potentials" auf akustische Reize bei kleinen Kindern entsprechend. Es kann jedoch keine Entscheidung getroffen werden, ob die in diesen Untersuchungen ermittelten evokierten Erregungsantworten im Gehirn des Fetus entstehen und von der Gehbfunktion des Fetus abhängen.

COCHLEAR MICROPHONIC RESPONSES TO PURE TONES IN MAN RECORDED BY A NON SURGICAL METHOD

N YOSHIE and K. YAMAURA

*From the Department of Otolaryngology (Chief Prof T Suzuki),
Faculty of Medicine, Shinsu University Matsumoto Japan*

A non surgical method of recording the cochlear microphonic (CM) responses in man has been developed, using new active electrodes in combination with an average response computer. One of these electrodes was needle electrode placed in the external acoustic meatus, another a fine 80-micron stainless steel wire electrode associated with a special cannula, which was placed on the promontory or the round window niche.

The procedure of the electrode placement was carried out completely without pain or bleeding. The acoustic stimuli were continuous pure tones or short bursts of pure tone. Subjects were volunteers with normal hearing and patients with conductive and sensorineural hearing loss. All the procedures of this experiment were made in sound proof room.

The results are condensed into the following

(1) All the subjects with normal hearing showed consistently and stably the cochlear microphonic response, recorded either from the external acoustic meatus or from the promontory

(2) When the short bursts of pure tone were presented, complex response consisting of cochlear microphonic, action potential (AP) and summing potential (SP), was recorded from the promontory and a complex response of the cochlear microphonic and action potential was recorded from the external acoustic meatus.

(3) When the continuous pure tones were presented, beautiful records of the cochlear microphonic responses were obtained both from the external acoustic meatus and from the promontory

(4) The form of the intensity function measured from the promontory in the normal subjects was in essential agreement with that reported for the round window recording in animals.

(5) Some of the intensity functions obtained from patients with severe sensorineural hearing loss showed the following abnormal patterns (a) reduction in the magnitude of the cochlear microphonic response, (b) distortions in the form of the intensity function (the nonlinear relation), and (c) parallel shift of the intensity function to the right side (reduced sensitivity).

(6) The sensitivity of the cochlear microphonics seemed to have some relation to the degree of the hearing loss in the audiogram.

(7) The non surgical method is applicable to routine clinical audiometry for differential diagnosis of sensorineural deafness, but empirical correlations must be established between the form of intensity functions and different types of sensorineural deafness.

(8) In middle ear impairment the less sensitive extratympanic method must be employed and the cochlear microphonics do not offer any advantages over other audiometric and otologic methods of diagnosis.

INTRODUCTION

From researches on cochlear electrophysiology in animals it is well known that an extracochlear electrode placed on the round window membrane of the animals can pick up three different electrical responses to acoustic stimuli from the cochlea viz. 1) the cochlear microphonics (CM), 2) the summing potentials (SP), and 3) the whole nerve action potential responses of the cochlear nerve (AP).

If one would hope for clinical use of these cochlear responses in man according to the higher demands of clinical audiology the practical problem of electrodes suitable for clinical use should be completely settled.

The history of the study of human cochlear responses began with a number of early works carried out by Fromm et al (1935), Andreev et al (1939), Perlman & Case (1941), and Lempert et al (1947-1950). They could record the CM with a gross electrode placed on the round window membrane by a surgical approach during operations on the ear. They observed that the round window membrane was the only suitable location for the electrode and it is possible to record the CM without major surgical procedure only in those rare instances in which the anatomic conditions are favorable. Unfortunately they could not demonstrate consistent cochlear responses that could be used routinely for objective audiology. It was concluded after these considerable efforts that the recording of the CM in man was not a practical clinical procedure (Lempert et al 1950). In view of the technical difficulty in obtaining a consistent response in man it is not surprising that the matter has not been considered in clinical otology since these early researches on the human CM.

During recent years the introduction of newly developed instruments for biomedical use consisting of a low noise high gain biomedical amplifier, a precise acoustic stimulator and a multichannel FM data recorder by Ruben and his colleagues (1959-1960), has permitted the stable and consistent recording of the CM and AP in man from an electrode placed on the round window and an application of this surgical technique by them (1961-1962, 1964-1967) has furnished us with a beautiful series of records illustrating changes in these cochlear responses (CM and AP) associated with various types of hearing loss. Ronis (1966), using the surgical method first applied a computer technique of averaging or summation to the measurements of the CM and AP in man. These results will be discussed later in this paper. Very few other reports in the literature dealt with the same problem (Krejci

et al 1949 1950 Brinkman & Tolk, 1961/1962 Flach & Seidel 1968), but Flach & Seidel (1968) reported the most extensive findings on the human CM in conductive deafness. In summary as long as surgical methods are employed there is a limitation of clinical application because a clinical routine test must be simple in practice as well as reliable and accurate in results. The operative procedure seems quite inadequate for systematic investigations on the human cochlear responses.

As regards the non surgical recording of the human CM, the first description as far as we know is found in the report of Lempert et al (1950), which was reviewed only briefly above. They passed a needle electrode through the tympanic membrane and made it contact closely with the bony promontory beyond the tympanic membrane. According to them, after the needle was withdrawn the tympanic membrane healed perfectly in a short time. The results with the CM were much inferior to the ones obtained with surgical placement on the round window membrane.

The second report was made by Gavilan et al (1964), using a high gain amplifier with sharply selective filters. They recorded the CM in man by an electrode placed on the tympanic membrane. Such a method was likely not only to need a great deal of skill in fixation of the active electrode on the tympanic membrane, but also to be much troubled with interference of a pseudo CM caused by the induction phenomenon of alternating current flow in the acoustic stimulating system.

These results in the non surgical recording of the CM did not meet the clinical requirements for practical use. The advent of an average response computer allowed a rapid advance in researches of various evoked responses in man (Rosenblith, 1959; Goldstein 1961 Katzman, 1964 Cox, 1963). Hilger et al (1963) first reported a method of recording nonsurgically the CM in cats by means of an average response computer. As mentioned above, the first use of the computer technique for measurements of the human CM was made by Ronis (1966). These averaging or summing methods of recording the CM (an alternating current responses) to periodic acoustic signals (pure tone stimuli) was completely based on the same principle that Miller et al (1964) used to measure extremely small signals with a waveform of periodic variation by a special purpose computer. This method can be well applied to the situations where noise interferes with measurements of periodic signals of very low levels in the area of physiological and psychological acoustics, on the basis of the theoretical considerations stated by Miller et al (1964). Although the non surgical method has been established for AP in man by means of an average response computer (Yoshie et al 1967 Yoshie, 1969 Sohmer & Feinmesser 1967 Portmann et al,

1967 1968 Spreng & Keldel 1968), as far as we know we have as yet very little information as to whether such averaging or summing method is valid for the non surgical recording of the human CM

A practical method has been developed for this purpose since 1968 in our laboratory. We have obtained nonsurgically these electrical cochlear responses by extracochlear electrodes placed in various regions of the ear in man. I.e. 1) the CM AP and SP were recorded by an electrode placed on the promontory and 2) the CM and AP were recorded by an electrode placed in the external acoustic meatus. The combined use of the computer and the extracochlear electrode which will be explained later in the following section furnished us the key to non surgical recording

The purpose of this study were (1) to outline the method of recording the human CM (2) to observe various findings on the CM in the normal ear and (3) to demonstrate changes in the CM from patients with various types of hearing loss.

METHODS

The general outline of this experimental method was essentially the same as that of Hilger et al (1965) and Ronis (1966), except for the following minor modifications: 1) an application of new extracochlear electrodes and 2) a versatile arrangement of the recording and stimulating equipments. We shall describe the steps of this method and a number of technical precautions necessary for the procedure.

Subjects

A total of 10 subjects with normal hearing and 30 patients with hearing loss of various types ranging in age from about 15 years old to about 65 years old were examined in respect to one or two of cochlear responses (CM and AP) by the non surgical method. Before these responses was recorded from them clinical otological examinations, such as otoscopic examination roentgenography: audiologic routine tests and so on had been employed

Apparatus

A simplified block diagram of all the apparatus is shown in Figure 1. The arrangement is classified into three systems, viz. 1) a stimulating system 2) a recording system and 3) a synchronising system of stimulation with responses.

The stimulating system is subdivided into 1) a pure tone generator and 2) a transient signal generator as illustrated in Figure 1. The former can produce two types of pure tone signals consisting of continuous sine waves and short bursts of sine waves. These signals can

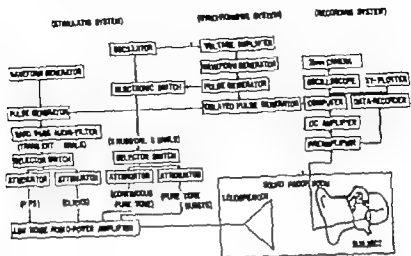

Figure 1. Block diagram showing arrangement of stimulating, synchronising, and recording apparatus.

be presented alternatively by a change over switch. The latter can produce two types of transient signals consisting of clicks and pips (filtered clicks), either of which can be selected by the change over switch. The pure tone generator was employed exclusively in this study because the main purpose of this experiment was to obtain the CM response to pure tone stimuli in man. The transient signals were preferable for recording the AP as has been reported (Yoshie et al, 1967).

The recording system comprised six components, as shown in Figure 1; an AC amplifier (SAN'EI MPA 203 TOKYO) with a flat frequency response curve over the frequency range 30 Hz to 1000 Hz, a DC amplifier (SAN'EI, MPA 203, TOKYO), an average response computer (SAN'EI MEDIAC 401 TOKYO), an oscilloscope (IWASAKI DS 5014 TOKYO), an X Y recorder (TOA DENPA XYR 1A, TOKYO), and photographing equipment for 35mm films (CANON MODEL IV TOKYO). The computer was used "on line" for averaging or summing the sample waveforms from the output of the biomedical amplifier system, with a window or analysis time of 31.25 msec, and with a summing or averaging number of 500 responses. Unfortunately the computer could not follow "on line" the CM at high frequencies above 2000 Hz. The CM responses were limited to a frequency range from 500 Hz to 1000 Hz in this experiment. The computer was triggered by a train of trigger pulses which were generated from the synchronising system in Figure 1. The triggering interval was taken at a period of 50 msec for recording the CM to the continuous tones and at a period of 200 msec for the short tone bursts. The summed or averaged waveforms of these responses

were displayed on the oscilloscope, and then these results were photographed on 35 films or written out on the X Y recorder immediately. The potential changes at the tip of the cochlear electrodes were introduced to the AC amplifier with a voltage gain of 1000 fold. The output of the amplifying system was connected to the computer as described above.

The synchronising system which plays the most important role in the function of the summing or averaging computer system comprised four instruments: a waveform generator (NIHON KOHDEN SW 1 TOKYO), a pulso generator (NIHON KOHDEN SP 1 TOKYO), a delayed pulso generator (NIHON KOHDEN SD 1 TOKYO), and a voltage amplifier as shown in Figure 1. In short this system produced the trigger pulses by which the computer could be driven in phase, correlating with the waveform of sine wave acoustic signals. Therefore, the sinusoidal waveform of the CM to sine wave tones could be summed up or averaged in phase. More detailed considerations on such correlating or synchronising system are available in earlier reports (Miller et al 1964; Hilger et al 1965; Ronis, 1966).

Acoustic Stimulation

The sound was presented by means of an open acoustic system in which a driver unit with a frequency range from 200 Hz to 4000 Hz served as an electro acoustic transducer. The driver unit was shielded completely to avoid electro magnetic interference with the recording system. It was located 30 cm lateral to the ear of the subject on the side of being tested. The frequency of the acoustic signals was limited to a range from 500 Hz to 1000 Hz, being varied by 100 Hz steps, because the frequency range of the computer was below 2000 Hz. The intensity of the signals was represented by the sound pressure level (in dB relative to 0.0002 dyne/cm²), which was measured with a calibrated condenser microphone connected to the sound level meter. The microphone was placed in similar position at 33 cm distance from the loudspeaker to the tympanic membrane of the subject in order to monitor the acoustic waveform. The intensity of the stimulus was controlled over a 100 dB range divided in 1 dB steps by adjusting a manually operated attenuator. The signals were given continuously or interruptedly. The tone bursts of variable duration were obtained by passing the continuous pure tone signals through an electronic switch as shown in Figure 1. Usually these signals were presented under conditions of a duration of 25 msec and a rise decay time of 5 msec or 10 msec.

Figure 2 shows the summed waveform of the two types of pure tone stimuli which were recorded from the output of the sound level meter in combination with the condenser microphone. These summed

Figure 2. Summed waveforms of acoustic signals. Each of the traces is an example of summing 100 sample waveforms from the output of the sound level meter connected with a condenser microphone.

sinusoidal waveforms are quite the same as single sample waveforms of the original tone stimuli. These records may be taken as guides for the pattern of summed response of the CM to the pure tone stimuli.

Electrodes

Two types of active electrodes were used for the extracochlear recording of the human CM AP and SP. One was a needle electrode with polyethylene coating except at the tip which was placed on the external acoustic meatus near the annulus tympanicus. Another was a polyurethane coated stainless steel wire, 80 microns in diameter which was placed on the promontory after the tip of the wire was passed through the tympanic membrane. Hereafter the terms "extratympanic" and intratympanic will be used synonymously with external acoustic meatal and promontory for convenience. The indifferent electrode was a disc electrode held in place on the ear lobe or on the mastoid region with electrolyte jelly.

1) The extratympanic electrode

The electrode of this type has been described in detail elsewhere (Yoshie *et al.*, 1967; Yoshie 1968). Usually after local infiltration anesthesia with 1 or 2% Citanest® Adrenalin mixture, the electrode

were displayed on the oscilloscope, and then these results were photographed on 35 films or written out on the X-Y recorder immediately. The potential changes at the tip of the cochlear electrodes were introduced to the AC amplifier with a voltage gain of 1000 fold. The output of the amplifying system was connected to the computer as described above.

The synchronising system which plays the most important role in the function of the summing or averaging computer system comprised four instruments: a waveform generator (NIHON KOHDEN SW 1 TOKYO), a pulse generator (NIHON KOHDEN SP 1 TOKYO), a delayed pulse generator (NIHON KOHDEN SD 1 TOKYO), and a voltage amplifier as shown in Figure 1. In short this system produced the trigger pulses by which the computer could be driven in phase correlating with the waveform of sine wave acoustic signals. Therefore, the sinusoidal waveform of the CM to sine wave tones could be summed up or averaged in phase. More detailed considerations on such correlating or synchronising system are available in earlier reports (Miller et al. 1964; Hilger et al. 1965; Ronis 1966).

Acoustic Stimulation

The sound was presented by means of an open acoustic system in which a driver unit with a frequency range from 200 Hz to 4000 Hz served as an electro acoustic transducer. The driver unit was shielded completely to avoid electro magnetic interference with the recording system. It was located 30 cm lateral to the ear of the subject on the side of being tested. The frequency of the acoustic signals was limited to a range from 500 Hz to 1000 Hz being varied by 100 Hz steps, because the frequency range of the computer was below 2000 Hz. The intensity of the signals was represented by the sound pressure level (in dB relative to 0.0002 dyne/cm²), which was measured with a calibrated condenser microphone connected to the sound level meter. The microphone was placed in similar position at 33 cm distance from the loudspeaker to the tympanic membrane of the subject in order to monitor the acoustic waveform. The intensity of the stimulus was controlled over a 100 dB range divided in 1 dB steps by adjusting a manually operated attenuator. The signals were given continuously or interruptedly. The tone bursts of variable duration were obtained by passing the continuous pure tone signals through an electronic switch as shown in Figure 1. Usually these signals were presented under conditions of a duration of 25 msec and a rise decay time of 5 msec or 10 msec.

Figure 2 shows the summed waveform of the two types of pure tone stimuli which were recorded from the output of the sound level meter in combination with the condenser microphone. These summed

soldered with a fine leading off copper wire for grounding at its basal end. The flange formed by the polyethylene drop serves to control the depth of the tip of the cannula and also to withstand sudden and large movements of the wire electrode when the cannula penetrates through the tympanic membrane into the tympanic cavity. Complete insulation should be maintained between the wire electrode and the hypodermic needle cannula.

The procedure for placement of the intratympanic electrode was divided into two steps. The first step was fixation of the cannula on the tympanic membrane. The same local infiltration anesthesia as described earlier was performed. The cannula was inserted in the posterior region of the pars tensa preferably at the marginal portion of the tympanic membrane up to the depth of the flange. There was suggestive evidence that the electrode might be located anywhere on the promontory at least near the round window niche. The magnitude of the CM response was large, sometimes strongest at this particular position of the tympanic membrane. This procedure was done under otoscopic inspection with an usual ear speculum, which was withdrawn from the external acoustic meatus after the insertion of the cannula on the tympanic membrane. The cannula was bonded firmly to the edge of the tragus with a strong adhesive.

The second step was to place the wire electrode on the bony promontory near the round window niche, passing through the cannula. The wire electrode could be run easily against the bony wall of the promontory by inserting it through the hole of the cannula inwards. After making close contact with the promontory the wire electrode was bonded firmly to the basal end of the cannula with the same adhesive. Finally the leading off wire of the electrode was connected to an input terminal of the AC preamplifier in combination with the indifferent electrode. The cannula of course was grounded.

In summary with regard to difficulties in practice, we believe anyone with only a little skill in paracentesis or myringotomy could make all these steps of the procedure without any uncomfortable accident to the patient. In our experience the patients have not complained of pain or bleeding in the ear during the procedure. In addition the perforation of the tympanic membrane healed in a very short time without any complications. It was not a task which called for much skill.

Procedure

The subject lay supine on a bed which was placed in an electrically shielded sound proof room under comfortable conditions of temperature and humidity. He was instructed to avoid unnecessary movements of the head and to remain relaxed during the series of acoustic

Figure 3. Schematic diagram of the intratympanic electrode

was placed in position on the posterior wall of the external acoustic meatus as medially as possible to the tympanic membrane. It was stuck firmly to the outer edge of the tragus with a strong bonding agent

2) The intratympanic electrode

Figure 3 illustrates a new intratympanic electrode which has been developed to allow continuous recording from the promontory for the time necessary for a series of these tests. In addition the electrode affords great facility for applying these cochlear responses (CM, AP and SP) to a routine clinical hearing test without any complicated surgical procedure. The basic structure of the electrode consists of a very fine stainless steel wire electrode which is insulated with a thin polyurethane coating and has a diameter of 80 microns, and a special outer cannula made of a hypodermic needle of about 8 cm in length and of 0.3 to 0.4 mm in diameter. The polyurethane coating is scraped in the region of 500 microns or slightly less at the tip of the wire electrode. A fine leading off copper wire, about 8.0 cm in length is soldered at the basal end of the electrode. Such a wire electrode enters the cannula through its basal end and then proceeds to the tip of the cannula until the tip of the wire electrode makes close contact with the promontory. The cannula is provided with a small flat drop of polyethylene at the distance of 0.5 to 1.0 mm from its tip. The polyethylene drop is formed by molting a short fragment of polyethylene tubing on the hypodermic needle. In addition the cannula is

soldered with a fine leading off copper wire for grounding at its basal end. The flange formed by the polyethylene drop serves to control the depth of the tip of the cannula and also to withstand sudden and large movements of the wire electrode, when the cannula penetrates through the tympanic membrane into the tympanic cavity. Complete insulation should be maintained between the wire electrode and the hypodermic needle cannula.

The procedure for placement of the intratympanic electrode was divided into two steps. The first steps was fixation of the cannula on the tympanic membrane. The same local infiltration anesthesia as described earlier was performed. The cannula was inserted in the posterior region of the pars tensa, preferably at the marginal portion of the tympanic membrane up to the depth of the flange. There was suggestive evidence that the electrode might be located anywhere on the promontory at least near the round window niche. The magnitude of the CM response was large, sometimes strongest at this particular position of the tympanic membrane. This procedure was done under otoscopic inspection with an usual ear speculum which was withdrawn from the external acoustic meatus after the insertion of the cannula on the tympanic membrane. The cannula was bonded firmly to the edge of the tragus with a strong adhesive.

The second step was to place the wire electrode on the bony promontory near the round window niche passing through the cannula. The wire electrode could be run easily against the bony wall of the promontory by inserting it through the hole of the cannula inwards. After making close contact with the promontory the wire electrode was bonded firmly to the basal end of the cannula with the same adhesive. Finally the leading off wire of the electrode was connected to an input terminal of the 4C preamplifier in combination with the indifferent electrode. The cannula, of course was grounded.

In summary with regard to difficulties in practice we believe anyone with only a little skill in paracentesis or myringotomy could make all these steps of the procedure without any uncomfortable accident to the patient. In our experience, the patients have not complained of pain or bleeding in the ear during the procedure. In addition, the perforation of the tympanic membrane healed in a very short time without any complications. It was not a task which called for much skill.

2) The intratympanic electrode

Figure 3 illustrates a new intratympanic electrode which has been developed to allow continuous recording from the promontory for the time necessary for a series of these tests. In addition the electrode affords great facility for applying these cochlear responses (CM AP and SP) to a routine clinical hearing test without any complicated surgical procedure. The basic structure of the electrode consists of a very fine stainless steel wire electrode which is insulated with a thin polyurethane coating and has a diameter of 80 microns and a special outer cannula made of a hypodermic needle of about 6 cm in length and of 0.3 to 0.4 mm in diameter. The polyurethane coating is scraped in the region of 500 microns or slightly less at the tip of the wire electrode. A fine leading off copper wire about 6.0 cm in length is soldered at the basal end of the electrode. Such a wire electrode enters the cannula through its basal end and then proceeds to the tip of the cannula until the tip of the wire electrode makes close contact with the promontory. The cannula is provided with a small flat drop of polyethylene at the distance of 0.5 to 1.0 mm from its tip. The polyethylene drop is formed by melting a short fragment of polyethylene tubing on the hypodermic needle. In addition the cannula is

Figure 4. The CM responses to 500 Hz pure tone 1 msec recorded both from the external acoustic meatus and from the promontory. The pure tone stimuli were given continuously. All the traces show the summed waveforms of summing 500 sample responses. In this and the following figures upward deflection indicated negativity of the meatus or the promontory with respect to the reference electrode. The subject was 25-year-old male, with normal hearing. All the summed responses were photographed on the face of cathode ray oscilloscope.

reported for animals (cf Stevens & Davis, 1938; Davis, 1951; Wever & Lawrence, 1954) and for human beings (Ruben et al 1959, 1960, 1961; Ronis, 1966).

The waveform of the CM response was distorted in a great degree at the low intensity of the stimulus, near a pseudo threshold or a detection threshold which has been discussed by several authors (Stevens & Davis, 1938; Davis, 1957; Wever 1959, 1966; McGill, 1959) by the contamination of background noise, as shown in Figure 4. As a rule the background noise interfered much more with the waveform of the CM response obtained by the extratympanic electrode than that obtained by the intratympanic electrode. The distortion of

stimulating runs. Short bursts of pure tone were delivered at an interval of 200 msec, and the responses to 500 tone bursts were summed "on line" in one run. In the case of continuous tone stimuli the responses were sampled every 50 msec by the computer and 500 sample responses were summed in one run. After all summing the responses to 500 stimuli in one run took 100 sec for the tone burst signals or 25 sec for the continuous tone signals, in addition to which one more minute was used for photographing or writing out the summed response and resetting the apparatus. It took about an hour or slightly more to terminate one series of experimental observations on the CM.

In this experiment choice between the extratympanic electrode and the intratympanic one was made quite arbitrarily but the authors intend to use the latter in their future work. The electrode placement was carried out easily in the sound proof room. After fixation of the electrode the DC resistance between the active and indifferent electrodes was measured. It was reasonable, for stable and consistent recording, that the value of the resistance was lower than 30 kilohms for the extratympanic electrode and lower than 15 kilohms for the intratympanic electrode. It was absolutely necessary as has been pointed out by Hilger et al (1965), to separate electrically the recording system from the stimulating system completely and to provide good grounds for the shields.

RESULTS

Waveforms

All the subjects with normal hearing have consistently shown CM AP and SP responses both to the continuous pure tones and to the short bursts of pure tone. These have been recorded both from the external acoustic meatus and from the promontory. The summed waveforms of the electrical cochlear responses to the continuous pure tones were simply sinusoidal and reproduced well the forms of the original acoustic signals, shown in Figure 2. This is convincing evidence that these alternating electrical potential responses as a result of acoustic stimulation of sinusoidal signals were the CM responses in man. Figure 4 shows the summed waveforms of the CM responses in man to the continuous pure tone stimulus, in which the simple sinusoidal form similar to the stimulus is maintained until the intensity reaches the high intensity of some 100 dB SPL. It is obvious from this figure that the magnitude of the CM response continues to increase as the stimulus intensity is increased up to a level of about 100 dB SPL. The quantitative relation of the magnitude of the CM response in man to the stimulus intensity will be described in detail later. These findings on the waveform of the human CM are in good agreement with those

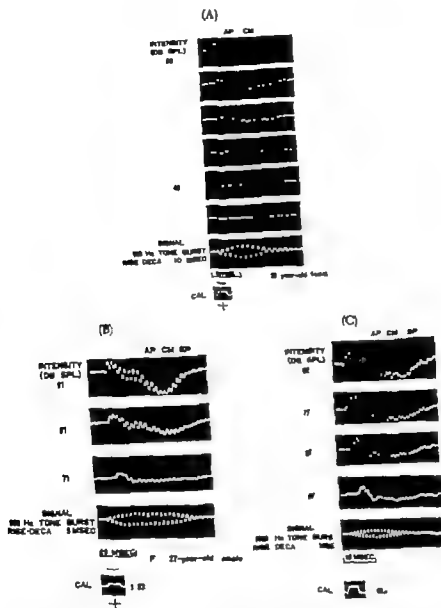

Figure 6. Composite responses to the tone bursts with frequencies of 600 Hz (A), 900 Hz (B), and 1000 Hz (C) recorded from the promontory in man (Y = 27 year-old female), showing the AP and CM (A) or the AP, CM, and SP (B and C). Each trace is the sum of 500 sample responses.

non surgical recording. In summary at high intensities no or little distortion of the summed waveform was revealed over frequencies from 500 Hz to 1000 Hz in gross appearance, and at low intensities, in contrast the distortion due to background noise was overwhelming.

On the other hand the waveform of the response to the short

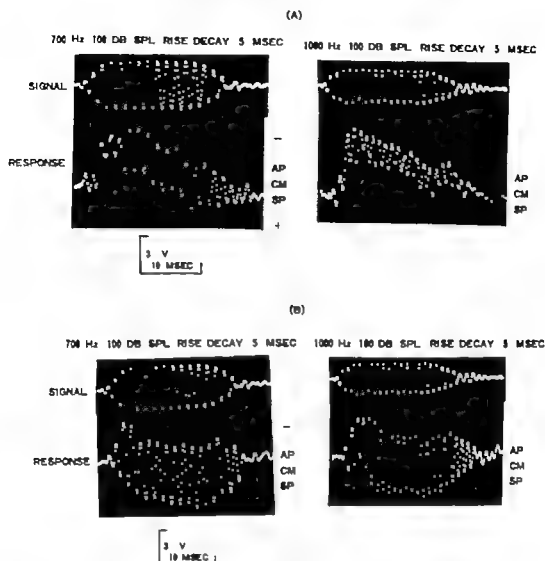

Figure 5. Complex responses to the tone bursts recorded from the promontory of human subjects ((A) S. Z. a 25-year-old male; (B) M. N. a 20-year-old female), showing the CM responses (700 Hz and 1000 Hz), the AP (the peaks and humps superimposed on the rising phase (A) or on the falling phase (B) of the SP response), and the SP response (upward displacement (A) or downward displacement (B) of the base line). Each trace is the sum of 500 sample responses.

the summed waveforms due to the background noise seemed to be the most serious kind of distortion in recording the CM nonsurgically by the computer method of summation. At high intensities, although the highest level was at best about 100 dB SPL, the summed waveforms were quite smoothly sinusoidal without a notch or hump or peak clipping over a frequency range from 500 Hz to 1000 Hz. The waveform distortion caused by the combination of the AP with the CM (cf. Stevens & Davis 1938; Wever & Lawrence 1954; Wever 1966) has not been confirmed in this experiment for reasons we believe of the distortion due to background noise which may be inevitable for the

Figure 7. Composite responses recorded both from the promontory and from the external acoustic meatus in man (Y. K., 20-year-old male). Both the intratympanic electrode and the extratympanic electrode were applied to the subject simultaneously. All traces are the sum of 800 sample responses.

proportions, supporting the view of Davis (1957). Although in order to obtain pure information exclusively as to the CM response in man the continuous acoustic stimulation by a pure tone is preferable to the short burst stimulation, the pattern in response to the latter seems to be available for making an overall estimate of the cochlear electrical responses (CM, AP and SP).

Sensitivity

As suggested by Wever & Lawrence (1954), and Wever (1959, 1966), the sensitivity of the CM responses in man was expressed as the sound pressure level (dB SPL) necessary to produce an arbitrary voltage of CM response, measured in the linear portion of the intensity function of the CM. Throughout this experiment the peak to peak amplitude of the summed CM responses displayed on the oscilloscope of the computer will be referred to as the amplitude or magnitude of the CM response. The sensitivity of the CM response was measured at levels of 0.1 microvolts, 0.3 microvolts and 1.0 microvolts, for frequencies of 500 Hz and 1000 Hz by both the extratympanic method and the intratympanic method. These results are listed in Table 1 in which the values (dB SPL) of the sensitivities represent the averages of 5 normal subjects together with the individual values for the intratympanic

bursts of pure tone differed in a great degree from that in response to the continuous pure tone. Figure 5 illustrates the time course and waveform of the summed response to the tone bursts. The pattern in Figure 5 involves an alternating current response which reproduces the sinusoidal waveform of the tone burst, as a main component of this complicated response. Such an alternating current response represents the CM response itself. Beside the CM response, the following changes in the waveform are observed: 1) negative or positive shifts of the base line of the tracings, and 2) negative peaks or humps superimposed at the beginning of a train of sinusoidal (CM) waves. Such distortions in combination with the CM response modifies the precise reproduction of the trapezoidal envelope of the tone burst as shown in Figure 5. These waveforms of the responses to the pure tone bursts from human beings are in very close agreement with those reported for animals by several investigators (Goldstein 1954; Pestalozza & Davis, 1956; Davis 1958, 1960; Davis et al. 1958 a, b; Ånggård 1965). The base line shift of the tracings suggests the SP. The polarity of the base line shift varied with the individuals. No systematic relation of the SP in man to the stimulating factors has been observed with the intratympanic electrode. Such inconsistency in the polarity of the base line shift might be caused by considerable variations in placement of the intratympanic electrode on the promontory.

Another important distortion is the negative peaks or humps, undoubtedly due to the admixture of the AP. The negative peaks (AP) were often differentiated well from the otherwise sinusoidal wave of the CM at high frequencies above 1000 Hz. The appearance of the AP response in man to the pure tone bursts was compatible with the results in animals reported by Stevens & Davis (1938) and Davis (1957).

Figure 6 shows the combined responses of the CM with the AP to the tone bursts from the human promontory. The proportion of the mixture of the AP and the CM varied with the frequency of the stimulus. The higher the frequency the more distinctly the AP could be distinguished from the CM. It was not surprising that the magnitude of the AP varied with changes in the rise decay time of the tone burst. The summed responses to the short burst stimuli from the external acoustic meatus were a mixture of the CM and the AP without the appearance of the SP. The magnitude of the summed responses obtained by the extratympanic electrode was at least about 5 to 10 times less than that obtained by the intratympanic electrode. Figure 7 illustrates differences in the waveforms of the complex responses between these two electrodes.

From these facts we have reached the working hypothesis that the extracochlear response in man to a short burst of pure tone was a complex response consisting of the CM, AP, and SP in uncertain

Figure 7 Cochlear responses recorded both from the promontory and from the external acoustic meatus in man (Y. K., 20-year-old male). Both the intratympanic electrode and the extratympanic electrode were applied to the subject simultaneously. All traces are the sum of 500 sample responses.

proportions, supporting the view of Davis (1957). Although in order to obtain pure information exclusively as to the CM response in man the continuous acoustic stimulation by a pure tone is preferable to the short burst stimulation, the pattern in response to the latter seems to be available for making an overall estimate of the cochlear electrical responses (CM, AP and SP).

Sensitivity

As suggested by Wever & Lawrence (1954), and Wever (1958, 1966), the sensitivity of the CM responses in man was expressed as the sound pressure level (dB SPL) necessary to produce an arbitrary voltage of CM response, measured in the linear portion of the intensity function of the CM. Throughout this experiment the peak to peak amplitude of the summed CM responses displayed on the oscilloscope of the computer will be referred to as the amplitude or magnitude of the CM response. The sensitivity of the CM response was measured at levels of 0.1 microvolts, 0.3 microvolts and 1.0 microvolts, for frequencies of 500 Hz and 1000 Hz by both the extratympanic method and the intratympanic method. These results are listed in Table 1 in which the values (dB SPL) of the sensitivities represent the averages of 5 normal subjects together with the individual values for the intratym-

TABLE 1 *CM sensitivity of the normal human ear as measured under two conditions (1) extratympanic recording from the external acoustic meatus and (2) intratympanic recording from the promontory*

Amplitude of CM in microvolts (peak to-peak)	Human CM sensitivity in dB SPL			
	500 Hz		1000 Hz	
	Meatus	Promontory	Meatus	Promontory
0.1	64 (55-74)	48 (40-59)	70 (64-77)	57 (50-61)
0.3	79 (71-86)	57 (49-66)	84 (79-97)	67 (59-73)
1.0	—	67 (58-80)	—	78 (68-82)

The sensitivity refers to the sound pressure level (dB SPL) at 500 Hz and 1000 Hz necessary to produce a constant potential (0.1 microvolt, 0.3 microvolts, or 1.0 microvolts) of the CM (see Text). The results of five subjects were averaged for the promontory recording, and those of seven subjects were averaged for the meatal recording. The number in each column from the second one to the fourth represents the average of the sensitivity with individual values of minimum and maximum in parentheses. The number in the first column indicates the voltage of the CM.

panic recording and the averages of 7 normal subjects together with the individual values for the extratympanic recording. Sometimes the potential of 0.1 microvolts was not high enough for accurate measurements of the magnitude of the CM responses because the distortions due to background noise was overwhelming. Such was the case that the sensitivity of 0.1 microvolts was estimated by a method of the linear extrapolation (Wever 1959, 1966; McGill 1959). After determining the intensity function of the CM as will be explained later in the section dealing with the intensity function, the measurements were extended downward to a level of 0.1 microvolts by extrapolating from the linear portion of the intensity curve at high intensities.

Table 1 shows that the sensitivity varies not only with the position of the electrode but with the frequency of the stimulus. The intratympanic electrode, as might have been expected, was more sensitive than the extratympanic one. The differences in the sensitivity of 0.1 microvolts between the two electrodes averages 16 dB for 500 Hz and averages 13 dB for 1000 Hz. Likewise the differences between them in the sensitivity of 0.3 microvolts averages 22 dB for 500 Hz and averages 17 dB for 1000 Hz. Overall the difference in the sensitivity between these electrodes on the average was about 20 dB. These differences represent the loss of the sensitivity caused by the extratympanic electrode.

Pseudo threshold

The lower limit of the potential at which the CM response became obscured by background noise was about 0.1 microvolts under favorable conditions of both the intratympanic electrode and the extratympanic electrode, using a summing or averaging number of 500 responses. Therefore, we chose the sensitivity of 0.1 microvolts as a measure of the lowest intensity that will produce a just detectable response from the trace on the oscilloscope, in preference to a conventional use of "thresholds" or "detection thresholds". The potential of the CM responses of 0.1 microvolts obtained from the subjects with normal hearing has fallen safely within a linear range of the intensity function as will be stated below. The linear extrapolation (Wever 1959, 1966) was applied to measurements of the sensitivity of 0.1 microvolts, as listed in Table I.

The visually detectable thresholds for the subjects with normal hearing ranged from about 40 dB SPL to about 60 dB SPL over frequencies from 500 Hz to 1000 Hz in the intratympanic recordings and ranged from about 50 dB SPL to about 70 dB SPL over the same frequencies in the extratympanic recordings. These results were in good agreement with those of the sensitivity of 0.1 microvolts. The sensitivity of 0.1 microvolts may be compatible with a "pseudo threshold" as designated by Davis 1957.

Strictly speaking, the CM is a continuous function of the intensity of the stimulus and does not have a threshold (Stevens & Davis, 1938; Davis, 1957; Wever 1959, 1966). With regard to the measurement of the threshold for the CM, Wever 1966 has laid much stress on the point that the detection threshold procedure has nothing to recommend it and should be eliminated from future research in this field.

The pseudo threshold or the sensitivity of a small response, however, seemed to be useful in analyzing and describing the CM response in man recorded by means of a computer for purposes of objective audiometry.

Intensity Functions

The magnitude or amplitude peak of the CM to continuous pure tones, but not to the short bursts of pure tone, was measured from the subjects with normal hearing as a function of the sound pressure level of the stimulus intensity over a range from a low level near subjects' thresholds to levels near 100 dB SPL, both by the extratympanic method and by the intratympanic method. The frequency of the stimulus ranged from 500 Hz to 1000 Hz. The magnitude was plotted on a logarithmic scale of the ordinate against the sound pressure level of the abscissa. This is commonly known as the intensity function of the CM. A large literature has published on the intensity function

Figure 8. Intensity functions of the CM responses at 500 Hz (A) and 1000 Hz (B) in man. Amplitudes (peak to peak) of the CM responses, recorded with the intratympanic electrode (heavy lines) and the extratympanic electrode (broken lines), are represented as a function of the sound pressure level of the stimulus (dB SPL). The indicated number of each curve identifies the individual.

in animals (*cf.* Stevens & Davis 1938 Tasaki et al 1952 a b 1954 Wever & Lawrence 1954 Davis 1951 1957 1958 a b Wever 1966), but few studies have been reported for human beings (Ronis, 1966 Ruben 1968).

Figure 8 shows intensity functions recorded both from the external acoustic meatus and from the promontory in man for two frequencies of 500 Hz and 1000 Hz. Figure 9 shows a set of intensity functions obtained from the external acoustic meatus over a range of frequencies from 500 Hz to 1000 Hz.

1) Form of the intensity functions

The form of the intensity functions varied to a great extent with the position of the electrode. In general a typical intensity function for responses from the promontory is nearly linear in relation with the sound pressure level of the pure tone until the intensity reaches some high level at which the curve departs from the linear relation (heavy lines in Figure 8 A B). The slope of the curve in the double logarithmic coordinates is very close to 1 (unit). The upper limit of the linear relation ranges approximately from about 90 dB SPL to about 100 dB SPL.

Our findings on the input output relation of the CM as recorded from the promontory are essentially similar to those previously reported

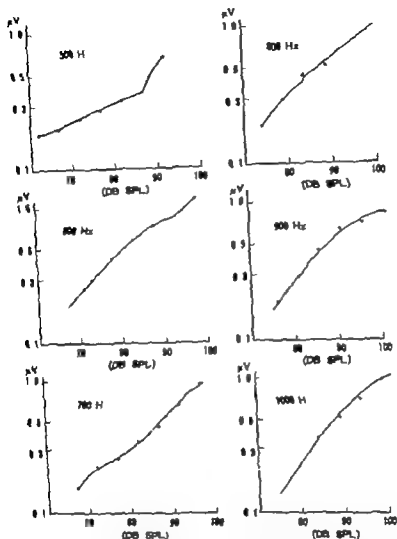

Figure 9. Intensity functions of the CM responses recorded from the external acoustic meatus (man K. L., 19-year-old female, normal hearing). The frequency of the stimuli: 500 Hz, 800 Hz, 1000 Hz, 1200 Hz, 1600 Hz, and 2000 Hz. Ordinates: Amplitude peak to peak of CM (microvolts). for the round window recordings in animals (*cf.* Stevens & Davis, 1938; Tasaki et al. 1955; a Wever & Lawrence, 1954; Kjørgaard 1963; Shiraiwa 1966). For the intratympanic recording, it seems reasonable to assume that when an electrode is placed in contact with the promontory it best records effectively from the hair cells near the basal end of the basal turn. This is mainly because the promontory is produced anatomically by the bulging basal turn of the cochlea and the electrode at this site reflects the activity of the hair cells in its

for the round window recordings in animals (cf Stevens & Davis, 1939; Taki et al 1954; a Weaver & Lawrence 1954; Anggård 1965; Shalwa 1966). For the intratympanic recording, it seems reasonable to assume that when an electrode is placed in contact with the promontory it best records effectively from the hair cells near the basal end of the basal turn. This is mainly because the promontory is produced anatomically by the bulging basal turn of the cochlea and the electrode at this site reflects the activity of the hair cells in its

immediate vicinity

On the other hand intensity functions for responses as recorded from the external acoustic meatus are not quite linear even at their lower ends (broken lines in Figure 8 A B and Figure 9). The slopes of the curves in the double logarithmic coordinates are significantly less than 1.0. The nonlinear relation to the stimulating intensity holds in general at frequencies of 500 Hz and 1000 Hz over a range of intensity from about 60 dB SPL to 100 dB SPL. This is a very important difference between the intratympanic and the extratympanic recordings. What the difference means appears to be more than a simple displacement of the curves to the right on the intensity axis such as might be expected from greater attenuation at the more remote electrode.

Such a nonlinear relation of the CM response as recorded from the external acoustic meatus may be explained as due to the remote position of the recording electrode and its different orientation with respect to the anatomical source of the generator potentials (the CM). Namely for the extratympanic recording an electrode is not applied to the cochlea directly but to the osseous portion of the meatus at a certain distance from the whole cochlea. The electrode in the meatus may record more effectively from more apical response areas in the basilar membrane involving the peak regions of the mechanical displacement than when the electrode is on the promontory. Consequently the response may represent the activity of all the hair cells which are operating nonlinearly in the more apical regions of the cochlea.

These observations lead to the conclusion that a general trend toward the linearity is observed from the intensity function for the intratympanic recording whereas the nonlinearity is common in the curves for responses recorded by the extratympanic electrode.

2) Nonlinearity and the maximum of the CM

Accurate measurement of the upper limit of the linear relation was impossible in this experiment because of the irregularities in the intensity functions. The estimated potentials of the levels at which the nonlinearity appeared in the intensity functions were ranged from approximately 2 microvolts to 40 microvolts for intratympanic recording and from 0.5 microvolts to 1.0 microvolts for extratympanic recording. The intensities corresponding to such potentials were approximately 80 dB SPL to 95 dB SPL.

The intensity functions for intratympanic recording in the subjects with normal hearing tend to be nonlinear and asymptotic at intensities of more than about 90 dB SPL. Although the increase of the intensity function was less rapid (nonlinear) at these high intensities in comparison with the linear increase at low intensities, all the curves except for a few cases did not attain a maximum of the CM at intensities up

(A)

Figure 10. Intensity functions of the CM responses in a patient with conductive deafness (chronic otitis media). Otologic findings: The ossicular chain was not disrupted. The eardrum was scarred and retracted with posterior perforation and suggesting the adhesions. (A) Audiogram. The audiometer which had the reference level of zero dB on the basis of the Japanese Industrial Standard (JIS) was used throughout this investigation. The JIS reference level approximated the ISO-1983 reference level. (B) Intensity functions at 100 Hz, 500 Hz, 700 Hz and 1000 Hz, measured with the extratympanic electrode from the external acoustic meatus, as a function of the sound pressure level.

to 100 dB SPL. These exceptional cases formed a horizontal plateau or a peak of the intensity function at an intensity of about 100 dB SPL. No attempt to determine the maximum of the CM was made in the present study. Gross estimation was tried simply by extrapolating the curve upwards along its asymptotic course. The estimated potential of the maximum of the CM ranged from 5 microvolts to 50 microvolts for intratympanic recording, and from 0.6 microvolts to 1.5 microvolts for extratympanic recording. No systematic relation of the maximum of the CM to the frequency of the stimulus was found. The intensity at which the maximum of the CM would be attained appeared always to be more than 100 dB SPL.

The CM Responses in Conductive Deafness

All the patients with conductive deafness were examined by the extratympanic method alone in this experiment. Efforts have been made to compare the intensity functions obtained from the patients whose hearing losses were more than 30 dB for frequencies of 500 Hz and 1000 Hz with those obtained from the normal subjects.

In general, the form of the intensity function in conductive deaf

ness scarcely differed from that in normal hearing except that the former shifted to the right on the abscissa. The results may be summarized by saying that the sensitivity of the CM in conductive deafness relates to the degree of hearing loss in the audiogram. The more the hearing loss increased the higher the intensity was required to produce the same level of the CM as obtained from the subjects with normal hearing. Quantitative correlation however between the sensitivity of the CM and the hearing loss of conductive deafness has not been settled in this study.

In conclusion an interesting example of the intensity function for a patient with chronic otitis media is illustrated in Figure 10 in which the slope of the input output functions is nearly 1.0 (unity), although the response is recorded from the external acoustic meatus. The reasonable interpretation may be that the electrical conducting pathways to the electrode have been modified by the middle ear adhesions or secretion of fluid in the middle ear. In the case of inflammation of the middle ear it has to be borne in mind that the conditions of electrical conduction in the tympanic cavity may vary greatly from those of the normal ears.

The CM Responses in Sensorineural Deafness

1) The intensity functions

Under such heading subjects were selected out of a number of patients who have suffered from sensorineural deafness diagnosed as cochlear origin by tests such as pure tone audiometry, speech audiometry, Bekesy audiometry, recruitment tests, and so on. The CM responses to the continuous pure tones with frequencies of 500 Hz, 600 Hz, 700 Hz, 800 Hz, 900 Hz, and 1000 Hz, were recorded both from the external acoustic meatus and from the promontory in these patients. The highest intensity of the pure tone stimuli was limited to a level of 100 dB SPL or slightly above.

Although great effort was made to determine the intensity function from all patients, a number of the patients with hearing reduced by more than 80 dB hardly responded at all even to the highest intensity of the stimulus. A few examples will show that the intensity function could not be measured.

Figure 11 is an example of no response to pure tone stimuli of 500 Hz and 1000 Hz, which was obtained from a patient who suffered from unilateral sudden deafness on the left side with a severe hearing loss of as much as 80 dB to 90 dB. In contrast he had normal hearing for the right ear with typical form of the intensity function.

Figure 12 displays another example a patient had long suffered from progressive bilateral sensorineural deafness. His audiogram showed a total hearing loss in the right ear and a residual hearing of 80 dB

Figure 11 The CM response recorded from the promontory of a patient with unilateral sudden deafness, showing no response in the affected ear

Figure 12 Residual CM response recorded from the external acoustic meatus of patient with bilateral severe sensorineural deafness. It is noticed that residual hearing over range of frequencies from 250 Hz to 1000 Hz is seen in his audiogram. All the summed waveforms are recorded from the left ear

115 to 90 dB HL for frequencies of 500 Hz and 1000 Hz in the left ear. No response was recorded from the right ear for the two frequencies. The left ear responded very slightly to the 1000 Hz tone at the intensity of 100 dB SPL. Such slight a response may be called a

residual CM response" on the analogy of a residual hearing in a pure tone audiogram. The residual response indicates the sensitivity (pseudo threshold) in this case of a severe hearing loss. But it was too small to plot the intensity function with any accuracy.

2) Patterns of the intensity function

We are far from offering a detailed explanation of the quantitative correlation between the audiologic pattern and changes in the intensity function. Therefore at the present time we merely classify various forms of the intensity functions.

One of the most intriguing forms was the same pattern as the intensity function obtained from subjects with normal hearing. This seemed to be associated with relatively slight hearing losses. Another was an abnormal pattern which was readily differentiated from the normal pattern by the following differences: 1) overall reduction in potentials of the CM, 2) distorted nonlinear form of the intensity function, and 3) overall shift of the intensity function to the right on the intensity axis. These changes are illustrated in the next section. Yet another was an incomplete pattern which seemed to be a transitional form from the normal pattern to the abnormal pattern, suggesting an early stage of abnormality.

The patterns of the intensity function in sensorineural deafness can be grouped in two categories: 1) the normal pattern and 2) the abnormal pattern with no linear segment. Almost all the patients with a moderate or severe hearing loss exhibited the abnormal pattern as might have been expected. However, the evidence was insufficient to define the quantitative change in the intensity function in sensorineural deafness any more positively.

3) Clinical cases

Four cases with sensorineural hearing loss serve as examples.

Case 1: a 20 year old female with streptomycin deafness, shown in Figure 13, showed a rapidly increasing hearing loss for frequencies above 4000 Hz, associated with normal hearing for all other frequencies. For all the frequencies except 1000 Hz the intensity functions measured by the extratympanic method showed the normal pattern. At 1000 Hz the intensity function was shifted slightly to the right and the curve had a nonlinear relation to the sound pressure level. The sensitivity of 0.3 microvolts was 80 dB SPL for a 1000 Hz tone and 75 dB SPL for all other tones. The potential of the CM response to the stimulus intensity of 100 dB SPL ranged from 0.7 microvolts to 0.6 microvolts for all frequencies. In summary, the intensity function for 1000 Hz showed an incomplete form of the abnormal pattern but the others showed the normal pattern.

Figure 13. Audiogram and intensity functions of the CM responses of patient (case 1) with streptomycin deafness. Each of the intensity functions was measured from the left ear, using the stratympanic electrodes.

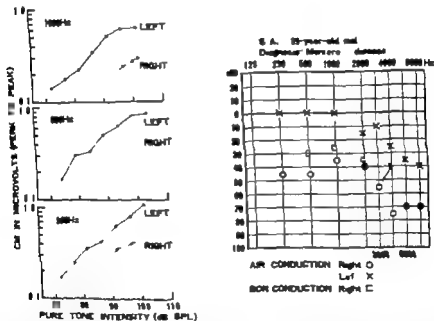

Figure 14. Intensity functions of the CM responses of patient (case 2) with Ménière's and an audiogram. Each of the intensity functions was measured both from the left ear and from the right ear simultaneously using electrodes placed approximately at the same positions as the external acoustic meatus.

Case 2, a 39 year old male with an unilateral hearing loss of the pin cochlear type in the left ear caused by Ménière's disease, was examined by the extratympanic method. An audiogram (Figure 14)

residual CM response on the analogy of a residual hearing in a pure tone audiogram. The residual response indicates the sensitivity (pseudo threshold) in this case of a severe hearing loss. But it was too small to plot the intensity function with any accuracy.

2) Patterns of the intensity function

We are far from offering a detailed explanation of the quantitative correlation between the audiologic pattern and changes in the intensity function. Therefore at the present time we merely classify various forms of the intensity functions.

One of the most intriguing forms was the same pattern as the intensity function obtained from subjects with normal hearing. This seemed to be associated with relatively slight hearing losses. Another was an abnormal pattern which was readily differentiated from the normal pattern by the following differences: 1) overall reduction in potentials of the CM; 2) distorted nonlinear form of the intensity function; and 3) overall shift of the intensity function to the right on the intensity axis. These changes are illustrated in the next section. Yet another was an incomplete pattern which seemed to be a transitional form from the normal pattern to the abnormal pattern, suggesting an early stage of abnormality.

The patterns of the intensity function in sensorineural deafness can be grouped in two categories: 1) the normal pattern and 2) the abnormal pattern with no linear segment. Almost all the patients with a moderate or severe hearing loss exhibited the abnormal pattern as might have been expected. However, the evidence was insufficient to define the quantitative change in the intensity function in sensorineural deafness any more positively.

3) Clinical cases

Four cases with sensorineural hearing loss serve as examples.

Case 1: a 20 year old female with streptomycin deafness shown in Figure 13 showed a rapidly increasing hearing loss for frequencies above 4000 Hz associated with normal hearing for all other frequencies. For all the frequencies except 1000 Hz the intensity functions, measured by the extratympanic method, showed the normal pattern. At 1000 Hz the intensity function was shifted slightly to the right and the curve had a nonlinear relation to the sound pressure level. The sensitivity of 0.3 microvolts was 80 dB SPL for a 1000 Hz tone and 75 dB SPL for all other tones. The potential of the CM response to the stimulus intensity of 100 dB SPL ranged from 0.7 microvolts to 0.8 microvolts for all frequencies. In summary, the intensity function for 1000 Hz showed an incomplete form of the abnormal pattern but the others showed the normal pattern.

Figure 13 Audiogram and intensity functions of the CM responses of a patient (case 1) with streptomycin deafness. Each of the intensity functions was measured from the left ear using the extratympanic electrodes.

Figure 14 Intensity functions of the CM responses in patient (case 2) with Ménière's disease and his audiogram. Each of the intensity functions was measured both from the left ear and from the right ear simultaneously using electrodes placed approximately at the same positions in the external acoustic meatus.

Case 2, a 39 year old male with an unilateral hearing loss of the pin cochlear type in the left ear caused by Ménière's disease, was examined by the extratympanic method. An audiogram (Figure 14)

shows a moderate flat hearing loss in the low and middle frequencies, associated with a steep fall of hearing loss in the high frequencies above 4000 Hz. The binaural loudness balance test at frequencies of 500 Hz and 1000 Hz gave complete recruitment in the right ear. Bekesy tracings were of small amplitude for a continuous pure tone stimulus in the affected ear. The CM responses were recorded from both ears under the same experimental conditions.

Figure 14 illustrates that for all frequencies the intensity functions in the right ear shift about 20 dB towards the right on the intensity axis parallel to those in the left ear. Thus the right ear was about 20 dB less sensitive than the left ear. Another interesting point was that there was no evidence for a rapid slope of the intensity function obtained from the ear with recruitment at frequencies of 1000 Hz and 500 Hz. Both the intensity functions measured from the normal ear and from the affected ear with recruitment were nearly parallel to each other. This is a very interesting point in addition to which the amplitude of the response recorded from the affected ear is not reduced for the reduced sensitivity shown by the audiogram.

On the other hand there were some exceptions in which the slope of the straight portion of the input output curve in the affected ear with recruitment was significantly less than unity. Such observations were not compatible with those shown in Figure 14. More experimental work is necessary for a conclusive explanation of the input output functions obtained from the ear with recruitment.

Case 3 a 20 year old female with a bilateral downward sloping hearing loss caused by progressive sensorineural deafness with unknown etiology was examined by the intratympanic method. As shown in Figure 15 a distinctive feature of the audiologic pattern was a severe hearing loss of more than 70 dB in the high frequencies above 2000 Hz. The intensity function could be measured only at 500 Hz, because of no response to the stimulus with higher frequencies above 600 Hz. The intensity function at 500 Hz is nonlinear and it attains a maximum at 0.9 microvolts. The value of 0.9 microvolts was significantly lower than the maximum obtained from the normal subjects (5 microvolts to 50 microvolts). The slope of the straight portion of the curve is significantly less than unity. These observations indicate that the input output relation of case 3 is the abnormal pattern with no linear segment.

Case 4 a 65 year old male with a bilateral flat hearing loss in presbycusis as shown in Figure 16 was examined by the intratympanic method. The intensity function could be obtained only at 1000 Hz. The curve in Figure 16 rises at first linearly and soon it becomes flat. The curve reaches its maximum at about 100 dB SPL. The maximum voltage is 0.4 microvolts. The sensitivity of 0.1 microvolts is about

Figure 15. Intensity function of the CM response at 500 Hz in patient (case 3) with bilateral progressive sensorineural deafness, and his audiogram. No response to the pure tones at 600 Hz, 700 Hz, 800 Hz, 900 Hz, and 1000 Hz, was noticed. The electrode was placed on the promontory in the left ear.

Figure 16. Intensity function of the CM response at 1000 Hz in a patient (case 4) with presbycusis, and his audiogram. The intensity function was measured from the promontory in the right ear. No response to the pure tones at 500 Hz, 600 Hz, 700 Hz, 800 Hz, and 900 Hz, could be recorded from this subject.

90 dB SPL, which is 30 dB less sensitive than the normal value. A residual CM response to the 500 Hz tone with an intensity of 100 dB SPL was recorded. No response to 800 Hz tone was recorded. The slope of the straight portion of the curve at 1000 Hz is about 1.0. These findings on the intensity functions in case 4 seemed to be quite

shows a moderate flat hearing loss in the low and middle frequencies, associated with a steep fall of hearing loss in the high frequencies above 4000 Hz. The binaural loudness balance test at frequencies of 500 Hz and 1000 Hz gave complete recruitment in the right ear. Bekesy tracings were of small amplitude for a continuous pure tone stimulus in the affected ear. The CM responses were recorded from both ears under the same experimental conditions.

Figure 14 illustrates that for all frequencies the intensity functions in the right ear shift about 20 dB towards the right on the intensity axis, parallel to those in the left ear. Thus the right ear was about 20 dB less sensitive than the left ear. Another interesting point was that there was no evidence for a rapid slope of the intensity function obtained from the ear with recruitment at frequencies of 1000 Hz and 500 Hz. The sensitivity of 0.1 microvolts is about

Figure 15. Intensity function of the CM response at 800 Hz in a patient (case 3) with bilateral progressive sensorineural deafness, and his audiogram. No response to the pure tones at 500 Hz, 700 Hz, 800 Hz, 900 Hz, and 1000 Hz, was noticed. The electrode was placed on the promontory in the left ear.

Figure 16. Intensity function of the CM responses at 1000 Hz in patient (case 4) with prosthesis, and his audiogram. The intensity function was measured from the promontory in the right ear. No response to the pure tones at 500 Hz, 600 Hz, 700 Hz, 800 Hz, and 900 Hz, could be recorded from this subject.

90 dB SPL, which is 30 dB less sensitive than the normal value. A residual CM response to the 500 Hz tone with an intensity of 100 dB SPL was recorded. No response to 800 Hz tone was recorded. The slope of the straight portion of the curve at 1000 Hz is about 1.0. These findings on the intensity functions in case 4 seemed to be quite

contradictory to those on case 2 and case 3. In case 4 changes in the intensity function was greater at the low frequency (500 Hz) than at the high frequency (1000 Hz), whereas in case 2 and case 3 the changes were more remarkable for the 1000 Hz tone than for the 500 Hz tone. Such differences in the CM responses between them are very probably due to differences in etiology and pathology of these cases of sensori neural deafness.

Before closing this section it should be pointed out that unfortunately the CM response for the frequency range from 2000 Hz to 8000 Hz could not be recorded throughout this entire experiment because the frequency range of the computer was limited to a low frequency range from 0 Hz to 1500 Hz. It will be essential to include in our future study a more detailed analysis of the CM in man for the higher frequencies.

DISCUSSION

Extracochlear electrodes as used in this study are entirely favorable for recording human cochlear responses because they are simple and the cochlea is completely uninjured. Davis (1957), however pointed out that extracochlear electrodes were in general quite inadequate for analysing intracochlear events because they recorded a mixture of AP, CM and SP and also a mixture of responses from various parts of the cochlea. Despite these serious limitations, the use of extracochlear electrodes is indispensably necessary for non surgical recording of the human cochlear potentials. As we have already seen there are important differences between the intratympanic and extratympanic methods for non surgical recording of the CM with respect to the pattern of the input output function. Namely the recording electrode on the promontory tends to give the linear input output relation with a slope of unity whereas the electrode in the external acoustic meatus produces the nonlinear relation with a slope of significantly less than unity. We may expect from these results that the hair cells near the basal end of the basal turn of the cochlear will contribute most readily to the potential seen at the promontory. On the contrary the external acoustic meatus may be the more favorable position of an electrode for recording effectively the contributions of the more apical hair cells in the broader regions of the basilar membrane than does the electrode on the promontory. In any event further studies into the question as to how much changes in various parts of the organ of Corti are recorded with these extracochlear electrodes are necessary.

Usually in the measurements of human cochlear potentials, effects of the physiological activities coming from other tissues and organs than the cochlea in the subject himself upon the response must be

taken into account. There are a number of possible causes of such distorting factors which may mask and distort the simple input output relation of the CM to the sound pressure level (cf Stevens & Davis, 1938; Wever & Lawrence, 1954; Hepp Reymond & Palin 1968). Among them actually three distorting factors may be commented on for human subjects: 1) physiological noise coming from the subject himself; 2) reflex contractions of the middle ear muscles, and 3) the combination of the cochlear nerve action potential responses. The effects of all these factors on the simple input output relation of the CM may vary of course, with the intensity of the stimulus, with the frequency of the stimulus, with the condition of the subject, and with the position of the electrode. Theoretically they are not to be confused with the deviation from linearity due to arrival at limits of intensity in the generation of electrical potentials (CM) in the individual hair cells (Stevens & Davis, 1938). Practically however it must be difficult in human experimentation to differentiate clearly the effect of one distorting factor from another.

Extensive contributions to clinical studies on the human cochlear potentials have been made by Ruben and his colleagues (1959, 1960, 1961, 1962, 1964, 1966, 1967). A method of graphic representation called the cochleogram (the sensitivity curve) has been developed by them. Ronis (1966) attempted to compare the intensity functions for responses recorded under preoperative conditions in otosclerosis with those recorded under the postoperative conditions. He observed a general increase in the CM output for all frequencies after stapedectomy. Furthermore, Ruben (1967) studied various changes in pattern of the intensity functions for patients with various hearing losses. These observations are at least partially in good agreement with our results.

In electrophysiological studies of cochlear lesions in animals, many investigators have observed at least two changes in the input output relations of the CM to the stimulus intensity: 1) a parallel shift of the linear portion of the intensity function to the right side and 2) reduction in the maximum CM voltage (cf Davis et al, 1953; Wever & Lawrence, 1954; Davis, 1957; Eldredge et al, 1957, 1958, 1959; Lawrence et al, 1959; Simmons & Beatty 1962; Wever 1966; Elliott, 1967; Ogawa 1968). It seems too early to say how suitable to the case of human beings these criteria in animals will prove. Clinical significance of the intensity function in sensorineural deafness would be a real puzzle in objective audiometry and would probably take much time to be resolved.

ACKNOWLEDGEMENTS

We wish to our gratitude to the director of the Department of Otolaryngology Professor Tokuro Suzuki, Shizuoka University, Matsumoto, for his interest and

generous support throughout this entire investigation.

We also wish to express our heartfelt thanks to Dr. Hallowell Davis, Central Institute for the Deaf, St. Louis, Mo., for his stimulating discussions and constructive criticism and for his careful review of the manuscript.

We are greatly indebted to Professor Dr. Ernst Lehnhardt, Universitätsklinik und Poliklinik für Hals, Nase und Ohren, Krankenhaus Hamburg Eppendorf, for his great help in making the German version of the manuscript.

We express our thanks to Miss Toshiko Oguchi for her skilful technical assistance.

ZUSAMMENFASSUNG

Zur Registrierung der Cochlearmicrophonics (CM)-Antworten beim Menschen wurde eine nichtchirurgische Methode entwickelt, bei der neue aktive Elektroden in Kombination mit einem Mittelwertrechner verwendet werden. Die eine der Elektroden war als Nadel gestaltet und wird im äusseren Gehörgang platziert, die andere besteht aus einem rostfreien 80 micron dünnen Stahl Draht und ist versehen mit einer speziellen Kanüle am Promontorium oder in der Rundfensternische gelegen. Das Anbringen der Elektroden ist für den Probanden schmerzlos und gelingt ohne Blutung. Als akustische Reize benutzt der Verf. reine Dauertöne und kurze Tonimpulse. Als Versuchspersonen normalhörende Freiwillige sowie Patienten mit Schalleitungs- und Innenohrschwerhörigkeit. Alle Untersuchungen fanden in einem schalldichten Raum statt. Die Resultate sind in folgender Weise zusammenzufassen:

1. Die normalhörenden Versuchspersonen zeigten regelmässig und beständig CM Antworten sowohl am äusseren Gehörgang als am Promontorium.

2. Bei Verwendung von Tonimpulsen wurden am Promontorium CM-Summenaktionspotential (AP)- und Summationspotential (SP) Antworten registriert und am äusseren Gehörgang CM- und AP Antworten.

3. Bei Verwendung von reinen Dauertönen waren die CM sowohl am äusseren Gehörgang wie auch am Promontorium registrierbar.

4. Die Form der Intensitätsfunktion am Promontorium stimmte bei normalhörenden Versuchspersonen vollkommen mit dem überein, was von Elektrodenmessungen am runden Fenster bei Tieren bekannt ist.

5. Einige der Intensitätsfunktionen von Patienten mit Innenohrschwerhörigkeit zeigten folgende abnorme Muster:

- (a) eine Verringerung der CM Grösse,
- (b) eine Verzerrung (nichtlineare Beziehungen),
- (c) eine parallele Verschiebung zur rechten Seite der Intensitätsfunktion hin.

6. Die Empfindlichkeit der CM scheint in Beziehung zu stehen zum Grad des Hörverlustes im Audiogramm.

7. Die nichtchirurgische Methode ist hinreichend praktikabel in der klinischen Routineaudiometrie zur Differentialdiagnose der Innenohrschwerhörigkeit.

CLINICAL USE OF COCHLEAR NERVE ACTION POTENTIAL RESPONSES IN MAN FOR DIFFERENTIAL DIAGNOSIS OF HEARING LOSSES

N. YOSHIE and T. OHASHI

*From the Department of Otolaryngology (Chief: Prof. T. Suzuki),
Faculty of Medicine, Shinshu University, Matsumoto, Japan*

The whole-nerve action potential response (AP) of the cochlear nerve in man was stably recorded either from the external acoustic meatus or from the promontory by a non surgical method, using an average response computer. Acoustic stimuli were either clicks or tone pips. Subjects were 8 normal volunteers, 15 patients with sensorineural deafness, and 2 patients with conductive deafness. Both the intensity function of the latency of N and of the amplitude of N were measured from all the subjects. There were many variations in pattern of these curves that might be produced by conductive or sensorineural hearing loss. On the basis of the working hypothesis of a double organization, these results were interpreted.

The general conclusions are as follows:

(1) For normal hearing, the input-output function of N included the two distinct segments, the L-curve and the H-curve, independent of the position of the electrode. Each of the segments might be generated by a different population of neurons and stimulated by a different class of sensory cells.

(2) For conductive hearing loss, the change in the latency and the amplitude seemed to be proportional to the degree of the hearing loss.

(3) For sensorineural deafness, three points may have clinical significance: (a) the overall reduction in amplitude of N, (b) the monotonically increasing form of the input-output function of N, in other words, the disappearance of the L-curve from the input-output relation, and (c) the prolonged latency of N.

(4) Our findings on the AP in man seemed to be practically identical with those reported for guinea pigs and cats.

INTRODUCTION

Recently a clinical method for non surgical recording of the human cochlear responses to acoustic stimuli has been developed in several laboratories independently by means of an average response computer (Yoshie et al. 1967, Yoshie, 1968, Portmann et al. 1967, 1968, Sohmer & Feinmesser 1967, Spreng & Keidel, 1968). The whole-nerve action potential response (AP) of the cochlear nerve in man has been recorded widely both from the external acoustic meatus and from the promontory with relative ease by the non surgical method. This is strong evidence

(dB SPL) of a 4000 Hz pure tone (for clicks) or a 4800 Hz pure tone (for tone pips) whose peak amplitude was the same the maximum amplitude of the clicks or the tone pips (cf. Dennerberg & Hirsh 1958 & Teas et al. 1962).

The subject lay on his back on a bed in an electrically shielded sound proof room equipped with an air conditioning system.

Electrodes were placed either on the external acoustic meatus or on the promontory in combination with a reference electrode on the earlobe. The electrode placement was performed under local infiltration anaesthesia in the posterior wall of the meatus. Electrodes fixed to the human body remained quite stable over long periods of time during the examination.

Responses to 500 successive clicks or tone pips were averaged or summed on line by an average response computer SANEI MEDIAC 401, with an analysis time of 31.25 msec. The summed waveform of the response was directly photographed on the face of an oscilloscope.

RESULTS

Normal Pattern of the AP in Man

Figure 1 is an example of the summed waveform of the AP recorded from the external acoustic meatus of a normal subject. The overall waveform is a series of peaks electrically negative with respect to the earlobe. This was quite the same as that recorded from the promontory near the round window. In addition, the form is essentially identical with those reported for animals and human beings (cf. Derbyshire & Davis 1935, Stevens & Davis, 1938, Teas et al. 1962, Ruben et al. 1960, Ronis, 1966).

The first and largest peak called " N_1 " is followed by the secondary small peaks, called " N_2 " and " N_3 ". Usually these peaks are monophasic. They are separated by intervals of about 1 msec. Frequently the N_1 showed a diphasic wave, in which a large negative peak (N_1) was followed by a small positive deflection. The N_1 is the main component of the AP and the others are secondary components. The observations reported in this study are made on N_1 .

The latency of N_1 was measured from the instant of arrival of the click at the eardrum to the peak of N_1 as shown in Figure 1. The time of its arrival was determined by placing a condenser microphone at 33 cm distance from the driver unit.

Figure 2 is the latency of N_1 recorded from the meatus as a function of click intensity. The averaged latency for 5 normal subjects is plotted against the peak equivalent sound pressure level of the stimulating clicks. The latency decreases nonlinearly with the increase of intensity. The upper and lower limits of distribution for sampling

to indicate that the AP as obtained from an extracochlear electrode placed somewhere remote from the round window may be applicable to a routine test for objective measurements of the overall functions in the cochlear nerve and the organ of Corti. As have been reported by Ruben and his colleagues (1960 1961 1963 1964 1966 1967), it would be impossible to record consistently the AP at some distance remote from the round window membrane in man without using the computer technique for averaging or summation.

In an earlier paper (Yoshie 1968), of particular interest might be the quantitative relationships between a few parameters of the AP in man and an intensity of stimulating clicks (1) the peak latency of N_1 was a very stable and consistent function of the sensation level of the click intensity and (2) the input output function of the peak to peak amplitude of N_1 includes two distinct segments or humps that are conveniently termed the L curve and the H curve respectively. The present study extends these observations to patients with sensorineural deafness and conductive deafness for practical purposes of clinical use. Consequently an attempt was made to record the AP in patients with hearing loss, either from the external acoustic meatus or from the promontory and then to measure both the latency of N_1 and its amplitude as functions of click intensity.

METHODS

A total of 25 subjects consisting of 8 with normal hearing 15 with sensorineural deafness, and 2 with conductive deafness, were employed in this study. For each of the subjects both audiological and otoscopic examinations were carefully carried out in advance.

The technique and the apparatus used in this study were the same as described fully in the article dealing with the human CM response in this special issue (1969) or in earlier papers (1967 1968), except for the following minor modifications of acoustic stimuli. Therefore only a brief outline need to be given of the experimental method.

Acoustic stimuli were either clicks or tone pips of 4800 Hz given at an interval of 160 msec by a driver unit which was placed 30 cm lateral to the ear tested. The electro acoustic transducer was completely shielded to avoid electrical artifacts on the records. Clicks were generated by applying a rectangular pulse of 0.1 msec duration to an audio amplifier. Tone pips of 4800 Hz were made by passing a rectangular pulse of short duration through a band pass filter which was set to the same cutoff frequency (4800 Hz) both for high and low pass (cf. Davis et al. 1951).

The intensity of the clicks and the tone pips was measured as the peak equivalent sound pressure level that is, the sound pressure level

individual values of the latency are shown by dashed lines in Figure 2. It is noticed that there are surprisingly small individual variations in latency. Such consistency of the latency has already been reported for cats by Ruben et al (1962). The intensity function of N_1 as obtained from the promontory was a perfect duplication of the Figure 2.

As regards the AP in normal hearing, we can safely say that the latency of N_1 depends not on the electrode position or the individual differences of subjects but on the intensity of the stimulus.

As illustrated in Figure 1 the amplitude of N_1 is defined as the height from the base line of the tracing to the peak of N_1 . The average for 5 measurements of the amplitude of N_1 at the same intensity of clicks was obtained for each of the 8 normal subjects. The averaged amplitude was used as data to be discussed. The responses were recorded at the following positions: (1) the promontory near the round window niche, (2) the promontory at some distance from the round window (3) the posterior wall of the meatus, 1 mm to 2 mm lateral to the annulus tympanicus, (4) the posterior wall of the meatus, 15 mm lateral to the eardrum, and (5) the outer end of the meatus.

Figure 3 is a set of input output functions of N_1 recorded at these various electrode positions as a function of the peak equivalent sound pressure level of the stimulating clicks. The amplitude in microvolts is plotted on a double logarithmic scale. The important point is that the input output curves are actually all similar in shape but differ chiefly by a factor of proportionality due to differences in attenuation at the different positions of recording. They also are practically similar to those reported for guinea pigs and cats (Rosenblith, 1959; Frishkopf & Rosenblith, 1958; Davis et al, 1958; Davis, 1960, 1961, 1962; Keldel, 1960, 1964).

Generally speaking, as shown in Figure 3, the input output curve rises rapidly at first from a threshold level of response and then it continues to rise rapidly up to a knee or a top of the first hump. The curve then rises along the second hump to the maximal level of output. The curve shows an inflection point at which the slope changes in the latency region from 3 dB to 80 dB peak equivalent SPL. The names of the L curve and the H curve have been suggested to designate the two curves (Yoshio, 1968).

The amplitude of N_1 at the meatus near the annulus tympanicus is reduced to about one tenth of those recorded near the round window niche. Accurate measurements of the output of N_1 at the outer end of the meatus were difficult to make, because the response was considerably attenuated, namely about one fifth of the output at the meatus near the annulus tympanicus.

Practically for the intratympanic recording from the promontory the electrode need not have been placed exactly on the round window

Figure 1 A typical summed waveform of the AP in man recorded at the external acoustic meatus by a non surgical technique. Responses to 500 clicks with an intensity of 100 dB peak equivalent SPL, given at an interval of 160 msec were summed by an average response computer with an analysis time of 31.25 msec. The subject was a 1 year old female with normal hearing. The vertical arrow in the upper left hand corner of the figure indicates the moment of arrival of the stimulating click. The base-line is an ideal line drawn simply by visual interpolation through the tracing of spontaneous activity to represent zero level of the amplitude of the response. In this and the rest of the figures upward deflection indicates negativity of the meatus (or the promontory) with respect to the reference electrode.

Figure 2 Latency of N_1 in man recorded at the external acoustic meatus in relation to the intensity of the stimulating click. The ordinate is the latency in milliseconds, and the abscissa is the click intensity in dB peak equivalent sound pressure level (see Text). Each point on graph represents the arithmetic average of 5 normal subjects. Five measurements on latencies of N_1 to the same intensity were made on each subject. Dashed lines indicate the extremely range of the individual latencies.

Figure 4. Latencies of N_1 obtained from 15 patients with sensorineural deafness as a function of peak equivalent sound pressure level. Each curve (heavy line) is interpolated smoothly by eye through the average of 3 measurements for responses to identical stimuli. An area surrounded by two dashed lines indicated the normal range of the latency of N_1 .

is so stable that it will be useful for objective measurements of the hearing loss caused by pure conductive deafness.

(b) Sensorineural deafness

Figure 4 shows a group of intensity functions of the latency measured from 15 patients with sensorineural hearing loss, whose degree of loss varied to a great extent. There are many individual variations in latency but a general tendency for these curves to shift upwards and to the right to a varying extent is exhibited. Namely the latency of N_1 seems to be prolonged in comparison with the normal range of the latency. But it may be too early to make a definite conclusion concerning the relation between the delay in latency of N_1 and the amount of hearing loss in sensorineural deafness.

Some of the curves show an abnormally rapid rise of the slope which is inversely related to the click intensity. Such remarkable delays seem to be characteristic of the latency in sensorineural deafness, because it has not been found in normal and conductive deafness.

Changes in amplitude

(1) Conductive deafness

The input output functions of N_1 were measured from the promontory (Figure 5) and the external acoustic meatus (Figure 6). For conductive hearing loss, the input output curve shifted to the right on

Figure 3. Input output functions of N_1 in man to clicks recorded at various positions of electrode placement. Amplitudes of N_1 are plotted on a double logarithmic scale against the peak equivalent sound pressure level. The eight curves are obtained from electrodes placed near the round window niche (A and B), on the promontory at some distance from the round window niche (C), at the external acoustic meatus near the annulus tympanicus (D, E, and F), on the meatus 15 cm from the cartum (G), and at the outer end of the meatus (H). Each curve is drawn smoothly by visual interpolation, based on the average of 5 measurements for responses to identical stimuli in each subject. The subject has normal hearing. The letters attached to each curve designate different subjects. The vertical dashed line drawn in the center of the figure marks approximate separation between the L-curve and the H-curve.

niche because the output of N_1 recorded by an electrode placed blindly somewhere on the promontory gave sufficiently accurate measurements. On the other hand for the extratympanic recording, an active electrode should be placed near the annulus tympanicus.

Abnormal Patterns of the AP in Man

Changes in latency

(a) Conductive deafness

The intensity function of the latency for conductive loss was similar to that for normal hearing except for a shift to the right along the intensity axis. The degree of the shift was proportional to the amount of hearing loss of the patients. A more extensive discussion of this problem is available in an earlier paper (1968). This simple relation

Figure 8. Variations in the input-output functions of N recorded from the external acoustic meatus of patients with various types of hearing loss. The parameter is designated as individual subject (letters) and as subjective threshold for click in decibels peak equivalent SPL (number in parentheses).

F.C. —with normal hearing. This curve represents typically two divisions of the input-output relation of N divided by an inflection point at 70 dB peak equivalent SPL, the L-curve and the H-curve.

K.S. —with normal threshold, except for bilateral C-3 dip, due to acoustic trauma. The form of the input-output function is the normal pattern. The L-curve is separated approximately from the H-curve by an inflection point at 85 dB peak equivalent SPL.

T.N. —with normal hearing, except for bilateral C-3 dip, with reduced threshold at 8000 Hz, due to streptomycin deafness. This curve is almost the same as just described above.

K.A. —with moderate high tone loss, due to acoustic trauma. There is an inflection point at about 85 dB peak equivalent SPL, but the L-curve is diminished.

K.N. —with bilateral downward sloping audiograms, due to head trauma. The curve rises monotonically up to plateau. The L-curve is not seen.

S.S. —with gradual high tone loss, showing moderate to severe hearing loss, due to sensorineural deafness of unknown etiology. The curve is monotonically increasing function with an abrupt slope.

S.A. —with unilateral flat audiogram with severe hearing loss, due to Ménière's disease. The curve rises abruptly in monotonic fashion up to maximal level.

H.H. —with severe sensorineural deafness, due to syphilis. The curve shows reduced amplitudes of N and monotonic rise.

M.K. —with conductive hearing loss, due to chronic otitis media. The curve shows both the L-curve and the H-curve. It is displaced to the right along the intensity axis.

Figure 5. Variations in the input-output functions of N recorded from the promontory of patients with various types of hearing loss. The four curves represented by a heavy line obtained from patients with sensorineural deafness (C. O. T. Y. S. Y. and M. N.). The curve represented by a dashed line is obtained from a patient with pure conductive hearing loss (Y. S.). The dotted curve at the top represents a typical form of the input output function obtained from a normal subject (A. F.). The numbers in parentheses indicate subjective thresholds for clicks in peak equivalent sound pressure levels. Each curve is interpolated smoothly by eye based on the average of 5 measurements for responses to identical stimuli.

the intensity axis. The degree of the shift seemed to be proportional to the amount of hearing loss. Both the L curve and the H curve remained normal.

(b) Sensorineural deafness

Both Figure 5 and Figure 6 illustrate typically various patterns of the input output functions in sensorineural deafness. All the curves were determined in response to clicks. These curves are represented by a smooth line rather than the actual data because this is the place to discuss a general trend of the input output functions in sensorineural deafness.

Figure 5 illustrates four cases with relatively severe hearing loss, and Figure 6 shows many cases including widely different degrees of hearing loss.

For sensorineural deafness, the typical form of the input output

Figure 8. Variations in the input-output functions of N_1 recorded from the external acoustic meatus of patients with various types of hearing loss. The parameter is designated as individual subject (letters) and as subjective threshold for click in decibels peak equivalent SPL (number in parentheses).

F.C.—with normal hearing. This curve represents typically two divisions of the input-output relation of N_1 divided by an inflection point at 70 dB peak equivalent SPL, the L-curve and the H-curve.

K.S.—with normal threshold, except for bilateral C-5 dip, due to acoustic trauma. The form of the input-output function is the normal pattern. The L-curve is separated approximately from the H-curve by an inflection point at 85 dB peak equivalent SPL.

T.H.—with normal hearing, except for bilateral C-5 dip, with reduced threshold at 8000 Hz, due to streptococcal deafness. This curve is almost the same as just described above.

K.A.—with moderate high tone loss, due to acoustic trauma. There is an inflection point at about 85 dB peak equivalent SPL, but the L-curve is diminished.

K.H.—with bilateral downward sloping audiogram, due to head trauma. The curve rises monotonically up to plateau. The L-curve is not seen.

S.S.—with gradual high tone loss, showing moderate to severe hearing loss, due to sensorineural deafness of unknown etiology. The curve is monotonically increasing (action with an abrupt slope).

S.A.—with unilateral flat audiogram with severe hearing loss, due to Ménière disease. The curve rises abruptly in monotonic fashion up to maximal level.

H.H.—with severe sensorineural deafness, due to syphilis. The curve shows reduced amplitudes of N_1 and monotonic rise.

M.K.—with conductive hearing loss, due to chronic otitis media. The curve shows both the L-curve and the H-curve. It is displaced to the right along the intensity axis.

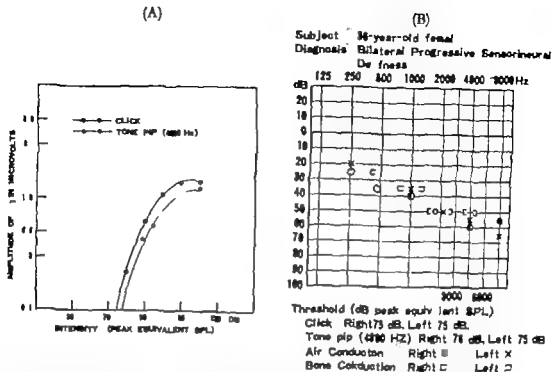

Figure 7 (A) Input output functions of N_1 to clicks and tone pips of 4800 Hz recorded from the external acoustic meatus of a patient with bilateral progressive sensorineural deafness, and (B) the audiogram. Measurements were made on the left ear. Both curves are monotonically increasing functions of the stimulus intensity. The forms of these two curves are approximately the same.

curve (Figure 5) is a monotonically increasing function with a steep slope. It rises very rapidly at first from the threshold response, and continues to rise sharply in a monotonic way up to a plateau or a maximal level of potential. Alternatively such a form may be explained as a disappearance of the L curve from the intensity function of N_1 .

Another important point is the reduction in amplitude of N_1 as demonstrated clearly in Figure 5. The amplitude of N_1 may be closely related to the amount of hearing loss at high frequencies above about 4000 Hz.

On the other hand there is a transitional form between the normal curve and the abnormal curve in Figure 5. Such a transitional pattern is shown in Figure 11 in comparison with both the typical pattern of normal hearing and the typical one of sensorineural hearing loss. For example, one of the curves, as labelled "T N" is almost the same as the normal pattern; another curve labelled "K A" shows a tendency for the L curve to diminish.

It appears well established for characteristic changes of the input output function in sensorineural deafness that (1) the reduction in amplitude of N_1 is significant and (2) the growth in amplitude of N_1 is rapid and monotonic as the click intensity is increased. In other words the disappearance of the L curve may be characteristic of

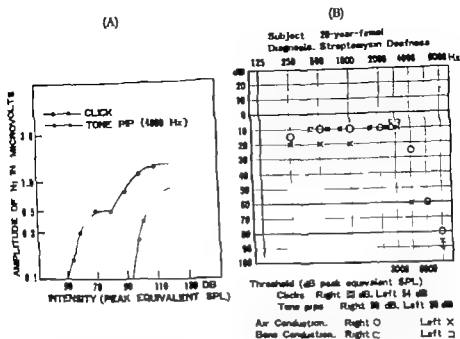

Figure 8. (A) Input-output functions of N_1 to clicks and tone pips of 4800 Hz recorded from the external acoustic meatus of patient with streptomycin deafness, and (B) the audiogram. The curve for clicks represents both the L-curve and the H-curve, but that for tone pips shows the latter alone.

sensorineural deafness. As evidence in support of this view a few examples will suffice.

Figure 7 illustrates a case a 36 year old female with bilateral progressive sensorineural deafness of unknown etiology. The AP was recorded at the meatus near the annulus tympanicus. The audiogram is a gradual high tone hearing loss. Both clicks and tone pips of 4800 Hz were used as acoustic stimuli.

The curves rise abruptly from a threshold response of 0.1 microvolts up to a maximal level of 1.5 microvolts. The dynamic range of these intensities were from 80 dB peak equivalent SPL to 110 dB peak equivalent SPL. The forms are typically monotonic. The curve for clicks is identical with that for tone pips of 4800 Hz.

Figure 8 illustrates a case, a 20 year-old female, with a bilateral abrupt high tone loss above 4000 Hz due to streptomycin deafness. The AP to clicks and tone pips of 4800 Hz was recorded at the meatus near the annulus tympanicus. Click stimuli resulted in the normal pattern of the input output function, but tone pips produced only the H curve associated with the reduction in amplitude. Such difference between clicks and tone pips of 4800 Hz may be due to the differences in the time course and the frequency spectrum of these transient

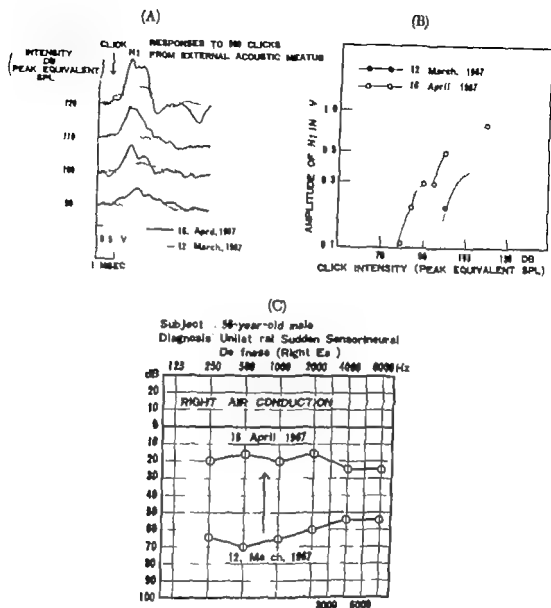

Figure 9. (A) Summed waveforms of the AP in sudden unilateral sensorineural deafness before and after treatment (B) Input output functions of N_1 and (C) the audiogram.

(A) Responses to 500 clicks recorded at the external acoustic meatus were summed by a computer. The waveforms represented by dotted lines show the AP recorded in the initial stage of sudden deafness (the most advanced stage of hearing loss). The waveforms drawn by heavy lines show the AP in the improved stage of hearing loss.

(B) Amplitudes of N_1 are represented as a function of peak equivalent SPL of the stimulating click. The amplitude in the initial stage of sudden deafness is greatly reduced.

signals (of Stevens & Davis 1938, Deatherage et al 1959, b, Davis 1961, Teas et al 1962). For this reason clicks may stimulate synchronously a larger portion of the organ of Corti than the tone pips of 4800 Hz. For the tone pips, the motion of the basilar membrane may be confined to the basal turn.

Figure 9 is a case of a 56 year old male with unilateral sudden sensorineural deafness. The audiogram shows a great deal of improve

ment of hearing loss after treatment, amounting to about 50 dB. In the initial stage with the most advanced hearing loss, the AP was remarkably reduced (Figure 9), and the input output curve is almost monotonic. In the improved stage with normal hearing the AP recovered fully and the curve represented both the L curve and the H curve.

DISCUSSION

The discussion will be centered upon the problem of the AP in sensorineural deafness. Three points may be commented on as essence of the criterion, for practical purposes, of the AP in man: (1) The marked delay in latency of N_1 (2) the marked reduction in amplitude of N_1 and (3) the monotonically increasing function of amplitude of N_1 with a steep slope in relation to click intensities.

Significance of prolonged latency of N_1

According to Deatherage et al (1959b), and Davis (1961), the latency of N_1 may comprise both the neural delay originating from asynchrony of impulses (*cf* Tasaki & Davis, 1955; Davis, 1957), and the traveling wave delay due to the space time pattern of the traveling wave on the basilar membrane (*cf* v. Békésy 1947). The neural delay seems to be the most important factor.

It may be reasonable to presume that various types of damage or injury in the cochlea particularly in the organ of Corti may give rise to greater asynchrony of impulses. Consequently the higher the asynchrony the more the latency of N_1 may be prolonged.

Deatherage et al (1959 b) observed in guinea pigs that some interferences (masking, local fatigue and local injection of drugs) in the basal turn prolonged the latency of the AP response. They concluded that the latency of N_1 for clicks was increased whenever the neurons of the basal turn could not respond synchronously.

Simmons and Beatty (1962) noticed in cats with acoustic trauma that many variations in latency of N_1 appeared in acoustic trauma. These observations on animals seem to be at least in part analogous to those on the human AP. Some types of sensorineural deafness may be responsible for the abnormally prolonged delay of N_1 .

Significance of reduction in amplitude of N_1

The reduction in amplitude of N_1 may well be interpreted by the concept of the volley principle (*cf* Derbyshire & Davis, 1933; Stevens & Davis, 1938; Tasaki 1954, 1957; Davis, 1957, 1960, 1961; Teas et al, 1966). According to them, the peak to peak amplitude of N_1 is fairly proportional to the number of fibers which are activated synchronously. The fact that the amplitude of N_1 in man was reduced

by the hearing loss due to sensorineural deafness may be in accord with the observations in guinea pigs by Pestalozza et al (1957), Eldredge et al (1958-1959), and Davis et al (1958).

Clinical use of the input output curve in man

As based on the widely held double organisation theory of the organ of Corti the two humps of the input output function for N_1 originate one from a small population with low threshold and the other from a larger one with high thresholds (Rosenblith 1954 a, b; Davis et al 1958; Davis 1960, 1961; Keidel 1960, 1964). Convincing evidence to support this hypothesis has been reported also for human beings (Yoshie 1968). The present results appear also to favor such a dual system of the sensory units in the periphery to the auditory pathway.

There have been many extensive observations on the input output functions of N_1 measured from guinea pigs and cats with cochlear injuries from drugs, acoustic trauma and venous obstruction (Davis et al 1958; Eldredge et al 1958-1959; Pestalozza et al 1957; Theisinger 1963; Stange et al 1963, 1964, 1966; Keidel 1960, 1964). These results in the animal experiments support the view that the appearance of the monotonic increase in amplitude of N_1 suggests a total or serious "subtractive loss" of the sensory units" belonging to the low threshold sensitive population (cf Davis, 1961, 1962; Yoshie 1968). If we accept this, the same may be said of the changes in the AP in man for sensorineural deafness.

It is of considerable clinical significance that the abnormal pattern could be found in the intensity functions of N_1 for sensorineural deafness. The correlation between the audiologic pattern of the audiogram and the pattern of the AP has not been assessed at the present time but its study presents an intriguing field for differential diagnosis of cochlear lesions.

Many more clinical cases with sensorineural hearing loss should be examined by the non surgical method however before a definite conclusion can be safely drawn about electrophysiological diagnosis for cochlear deafness and cochlear nerve deafness.

ACKNOWLEDGEMENTS

We wish to express our gratitude to the Director of the Department of Otolaryngology, Professor Tokuro Suzuki, Shizuoka University, Matsumoto, for his interest and generous support throughout the entire investigation.

We also wish to express our sincere thanks to Dr Hallowell Davis, Central Institute for the Deaf, St. Louis, Mo. for his constructive criticism and valuable discussions and for his helpful correction.

We are greatly indebted to Professor Dr Ernst Lohnhardt, Universitätsklinik

und Poliklinik für Hals-, Nasen- und Ohrenkrankheiten Hamburg Eppendorf
for making the German version of the manuscript.

ZUSAMMENFASSUNG

Das Summenpotential des Hörnervens beim Menschen (AP) wurde entweder vom inneren Gehörgang oder vom Promontorium mit Hilfe einer nichtinvasiven Methode und unter Verwendung eines Mittelwertrechners registriert. Als akustische Reize wurden Clicks und Tonimpulse verwendet. Als Probanden dienten 8 Normalhörende, 15 Patienten mit Innenohrschwerhörigkeit und 2 Patienten mit Mittelohrschwerhörigkeit. Sowohl die Intensitätsfunktion der Latenz von N als auch die Ausgangsfunktion der Amplitude von N wurden bei allen Versuchspersonen gemessen. Es fanden sich viele Varianten im Muster dieser Kurven, wahrscheinlich bedingt durch den Mittelohr bzw. Innenohr Hörverlust. Diese Resultate werden auf dem Boden der Duplizitätstheorie diskutiert.

Zusammenfassend ergab sich:

1. Für Normalhörende sich die Eingangs-Ausgangsfunktion von N einschliesslich der L-Kurve und der II-Kurve unabhängig von der Lage der Elektrode. Jedes der Segmente kann seinen Ursprung haben in der verschiedenen Population der Neurone und ausgelöst sein durch eine unterschiedliche Stimulusart.
2. Bei Mittelohrschwerhörigkeit scheint die Änderung in der Latenz und der Amplitude proportional zu sein dem Grad des Hörverlustes.
3. Bei der Innenohrschwerhörigkeit sollten drei Punkte als grundsätzliche Kriterien für den klinischen Gebrauch beachtet werden: a) die Gesamtreduktion der Amplitude von N, b) die gleichförmige Anstiegsform der Eingangs-Ausgangsfunktion von N₁, mit anderen Worten das Verschwinden der L-Kurve aus der Eingangs-Ausgangs-Beziehung, und c) die verlängerte Latenz von N₁.
4. Unsere Befunde am AP beim Menschen sind offenbar weitgehend identisch mit jenen, die am Meerschweinchen und von der Katze bekannt sind.

MYOGENIC EVOKED POTENTIAL RESPONSES TO CLICKS IN MAN

N. YOSHIE and T. OKUDAIRA

*Department of Otolaryngology, Faculty of Medicine
Shinshu University, Matsumoto, Japan*

Human myogenic potentials evoked by clicks have been recorded, both from the external acoustic meatus and from the post auricular region by means of an average response computer. The configuration of the response was triphasic: a negative-positive-negative wave with extremely short latency of the peaks (about 10 to 25 msec). The focus of the response seemed to be localized in a restricted area of the post auricular region. It was a relatively consistent and low threshold response. The magnitude of the response was amplified to a great extent by the forward flexion of the neck. The post auricular response was interpreted to be cochleo-myogenic in origin.

In short, the post auricular response could be used as an indicator of objective audiometry. Furthermore, in principle, there is a possibility that the response may be applied in an electrophysiological method of differentiating various oto-neurogenic disorders associated with lesions in the brain stem.

INTRODUCTION

Since the human "fast" evoked response to acoustic stimuli was first recorded extracranially by means of an averaging or summing computer method which was originated by Geisler et al. (1958), and Geisler (1960), various types of fast evoked response have been recorded differently from the scalp, from the neck, and from all the extremities by many investigators (Bickford et al. 1963 a, b; 1964; Kiang et al. 1960; Mart, 1963; 1965; Davis et al. 1964; Jacobson et al. 1964; Cody et al. 1964; Borsanyi, 1964; Borsanyi & Blanchard, 1964; Davis, 1965; Lowell, 1965; Goldstein, 1965; Goldstein & Rodman, 1967; Rubm et al. 1967; Celesta et al. 1968).

There is, as a matter of fact, much argument among the authors about the origin and pathway of the fast evoked response. Davis and his associates (1964; 1965 a, b; 1966) have already designated a short latency evoked response occurred during the first 50 msec following an acoustic stimulus as the "fast" evoked response in order to make a clear contrast to a long latency evoked response with a peak latency of 50 to 300 msec which was called the slow vertex potential evoked

The subject was seated comfortably in a reclining chair in a sound proof room. Usually the head was held natural in an upright position during a test run of 3 to 5 minutes. For the purpose of alterations in the muscular tone or tension of the head and neck muscles, he was instructed either to hold down the head as low as possible, or to hold the head well back during the test run when necessary. No extrinsic traction was applied to the head in any direction by means of mechanical maneuvers. As a result of these head positions, forward and backward flexions of the neck were obtained. Additional observations were carried out on a few subjects who lay in a supine position on a bed, resting the head on a pillow.

Usually needle electrodes for EEG recording were applied to the subjects. It was inserted hypodermically 5 mm to 10 mm from the surface of the skin at the recording site and then it was fixed firmly on the same place with an adhesive silicon tape for medical use. In case of necessity disc electrodes with EEG jelly were used for an active electrode. It was held in place on the skin with the same adhesive tape.

Active electrodes were placed at various portions of the periauricular region including the external acoustic meatus, with a reference electrode placed on the ear lobe. A ground electrode was placed on the center of the forehead. The distribution of the active electrode will be shown later in the section dealing with the experimental results.

Recording apparatus comprised basically four components: a bio medical amplifier (SAN'EI MPA 203 TOKYO), an average response computer (SAN'EI, MEDLAC 401 TOKYO), an oscilloscope (IWASAKI DS 5015, TOKYO), and a photographing system (CANON PHOTO OSCILLOSCOPE UNIT TOKYO).

Electrical responses picked up from the electrodes were led into the amplifier with a flat frequency characteristic from 20 Hz to 500 Hz. The output of the amplifier was fed into the average response computer with an analysis time of 6.5 msec or 125 msec. The computer summed on line in sequence 200 to 500 samples of the amplified electrical response to each of the acoustic stimuli. The summed waveform of the responses to 200-500 clicks was displayed on the oscilloscope and photographed by a 35 mm camera.

Stimulating apparatus comprised basically four components: a pulse generator system (NIHON KOJIDEN MSE-40 TOKYO), and audio amplifier (SONY 3120 A TOKYO), an attenuator and electroacoustical transducers composed of an electrically shielded earphone and a shielded loud speaker.

Acoustic stimuli were clicks originating from a square pulse of 0.1 msec duration produced by the pulse generator system. Clicks were given either monaurally through the earphone or binaurally through

response. In general the fast evoked response may be regarded as a composite response of myogenic evoked potentials and neurogenic evoked potentials (Mast, 1963, 1965; Davis et al, 1964, 1968; Ruhm et al, 1967). However on the basis of convincing evidence reported by Bickford et al (1963 a, b, 1964), and Cody et al (1964), currently the view is widely held that the major component of the fast evoked response is myogenic in origin and the name "sonomotor response" or "audiomotor response" was by them suggested to designate the response.

Apart from the puzzling problem concerning the physiological significance of the sonomotor response, there is still the question whether it is valid and reliable as an indicator of hearing suitable for clinical audiometry.

Nowadays at least three types of sonomotor response have been differentiated viz. (1) the inion response (Bickford et al, 1964; Cody et al, 1964), (2) the short latency vertex and parietal response (Mast, 1963, 1965; Goldstein, 1965; Goldstein & Rodman, 1967), and (3) the post auricular response (Kiang et al, 1963; Jacobson et al, 1964). As to clinical application Bickford et al (1964) maintained that the inion response can not be used as a valid index of hearing function because the reflex is likely to originate from the vestibular but not the cochlear receptors of the labyrinth. In addition the inion response is a high threshold response.

In regard to the short latency vertex and parietal response, Mast (1965) observed that it was much more stable and constant at moderate stimulus levels than was the inion response. Recently Goldstein & Rodman (1967) have obtained evidence that it may be of great value in determining threshold sensitivity in man. Lowell (1965), however stated that the slow Vertex potential response seemed to serve much better than the fast evoked response.

Finally the post auricular response as first reported by Kiang et al (1963), was a variable but low threshold response. There is as yet little information as to whether the response can be used to measure human hearing function.

Recently we also have observed that the same response, recorded at the external acoustic meatus and the post auricular region is a relatively consistent response, sensitive to weak acoustic stimuli. For this reason we will describe characteristics of the post auricular response and its interpretation.

METHODS

Observations on the post auricular response were carried out on a number of normal hearing adults and a few patients who suffered from severe sensorineural deafness associated with normal vestibular function.

The subject was seated comfortably in a reclining chair in a sound proof room. Usually the head was held natural in an upright position during a test run of 3 to 5 minutes. For the purpose of alterations in the muscular tone or tension of the head and neck muscles, he was instructed either to hold down the head as low as possible, or to hold the head well back during the test run when necessary. No extrinsic traction was applied to the head in any direction by means of mechanical maneuvers. As a result of these head positions, forward and backward flexions of the neck were obtained. Additional observations were carried out on a few subjects who lay in a supine position on a bed resting the head on a pillow.

Usually needle electrodes for EEG recording were applied to the subjects. It was inserted hypodermically 5 mm to 10 mm from the surface of the skin at the recording site, and then it was fixed firmly on the same place with an adhesive silicon tape for medical use. In case of necessity disc electrodes with EEG jelly were used for an active electrode. It was held in place on the skin with the same adhesive tape.

Active electrodes were placed at various portions of the periauricular region including the external acoustic meatus, with a reference electrode placed on the ear lobe. A ground electrode was placed on the center of the forehead. The distribution of the active electrode will be shown later in the section dealing with the experimental results.

Recording apparatus comprised basically four components: a bio-medical amplifier (SAN'EI MPA 203 TOKYO), an average response computer (SAN'EI MEDIAC 401 TOKYO), an oscilloscope (IVASAKI DS 5015, TOKYO), and a photographing system (CANON PHOTO OSCILLOSCOPE UNIT TOKYO).

Electrical responses picked up from the electrodes were led into the amplifier with a flat frequency characteristic from 20 Hz to 500 Hz. The output of the amplifier was fed into the average response computer with an analysis time of 62.5 msec or 125 msec. The computer summed on line in sequence 200 to 500 samples of the amplified electrical response to each of the acoustic stimuli. The summed waveform of the responses to 200-500 clicks was displayed on the oscilloscope and photographed by a 35 mm camera.

Stimulating apparatus comprised basically four components: a pulse generator system NIHON KOHDEN MSE 40 TOKYO, and audio amplifier SONY 3100 A TOKYO, an attenuator and electroacoustical transducers composed of an electrically shielded earphone and a shielded loud speaker.

Acoustic stimuli were clicks originating from a square pulse of 0.1 msec duration produced by the pulse generator system. Clicks were given either monaurally through the earphone or binaurally through

Figure 1 Summed waveform of the myogenic evoked response recorded from the post auricular region (just behind the pinna). Responses to 500 clicks were summed by the computer. The subject, a normal hearing young adult, was seated in a reclining chair holding his head in a natural upright position. In this and the rest of the figures, upward deflection indicated negativity of the active electrode (the post auricular region or the external acoustic meatus) with respect to the ear lobe.

the loudspeaker located at a distance of 1 m in front of the subject. Unless otherwise stated the interval of acoustic stimulation was 250 msec (4 clicks per second). The intensity of clicks was conveniently represented in terms of sensation levels (SL), i.e., decibels above subjective threshold for each subject. The subjective threshold for clicks was measured for all the subjects before the physiological examination.

RESULTS

As a result of click stimulation a short latency evoked response during the first 30 msec after the acoustic stimulus was recorded both from the external acoustic meatus and from the post auricular region in normal hearing subjects. The response was easily and consistently recorded when the subject was either seated in a chair holding his head upright or lying on his back on a bed resting his head comfortably on a pillow.

Figure 1 illustrates a typical summed waveform of the response consisting of three deflections: i.e., the first negative deflection with a peak latency of 8 to 15 msec, the first positive deflection with a peak latency of 13 to 20 msec, and the second negative deflection with a peak latency of 20 to 30 msec respectively with reference to the ear lobe. These deflections (peaks) are conveniently designated by the

Figure 2. Summed post-auricular responses to clicks as a function of the stimulus intensity. Each trace is the summed waveform of responses to 500 clicks. symbols of small letters n_1 , p_1 and n_2 respectively in order to avoid confusion with the peaks of the slow Vertex potentials represented by the capital letters P_1 , N_1 , N_2 etc. (cf Davis and his associates, 1964-1966). The mean peak latencies at high click intensities above 60 dB SL were about 12 msec for the n_1 , about 18 msec for the p_1 and about 25 msec for the n_2 . The positive peak, p_1 was most prominent among these peaks. There were slight individual differences in latency but the response obtained from the same place in the same individual gave stable and reproducible latencies of the peaks. As the click intensity increased from a threshold level up to high levels of more than 100 dB SL, the peak latency was reduced to a small extent by about 3 to 5 msec. A prolongation of the latency was distinct near threshold levels.

As shown in Figure 4, there was a general trend that the peak to peak amplitude such as the n_1 to p_1 amplitude or the p_1 to n_2 amplitude was increased with the increase of the click intensity. The increase of the amplitude was rapid and remarkable at higher

symbols of small letters n_1 , p_1 and n_2 respectively in order to avoid confusion with the peaks of the slow Vertex potentials represented by the capital letters P_1 , N_1 , V_1 etc. (cf Davis and his associates, 1964, 1968). The mean peak latencies at high click intensities above 80 dB SL were about 12 msec for the n_1 , about 18 msec for the p_1 and about 23 msec for the n_2 . The positive peak, p_1 was most prominent among these peaks. There were slight individual differences in latency but the response obtained from the same place in the same individual gave stable and reproducible latencies of the peaks. As the click intensity increased from a threshold level up to high levels of more than 100 dB SL, the peak latency was reduced to a small extent by about 3 to 5 msec. A prolongation of the latency was distinct near threshold levels.

As shown in Figure 2, there was a general trend that the peak to peak amplitude such as the n_1 to p_1 amplitude or the p_1 to n_2 amplitude was increased with the increase of the click intensity. The increase of the amplitude was rapid and remarkable at higher

Figure 3. Amplitude (the p_1 to n peak) of the post auricular response as a function of click intensity. Each point is the average of amplitudes for 8 normal subjects.

intensities than 50 to 60 dB SL. Such a rapid growth of the amplitude at high intensities of clicks appeared to be characteristic of the post auricular response.

The magnitude of the post auricular response even to an identical acoustic stimulus varied to a great extent across subjects across states of the subject and across electrode placement. For this reason it must be borne in mind that a conventional representation of the input output function of the amplitude as demonstrated in Figure 3 is nothing but a rough approximation of the growth of the curve. This input output curve was determined by averaging the data on 8 normal subjects. The slope of the curve is very rapid at high intensities above 60 dB SL.

Figure 4 exemplifies a raw waveform of the post auricular response in a single sweep of the oscilloscope. Such a single response was frequently recorded in a limited area just behind the pinna for an intense click stimulus, from a subject flexing his head and neck in a forward direction. No response to moderate and weak stimuli was seen in a single sweep of the oscilloscope.

The response threshold was defined as the intensity (dB SL) at which the summed response to 500 clicks could be visually detected from background noise of the tracing. For the post auricular response it ranged from 0 dB SL to 20 dB SL in normal hearing subjects.

The magnitude of the response varied from subject to subject. For

Figure 4. Single response to one click recorded from the post auricular region. The subject, a normal hearing young adult, held down his head as low as possible. The active electrode was placed just behind the pinna. This was photographed from single sweep of the oscilloscope.

example, at an intensity of 90 dB SL the n_1 to p_1 amplitude ranged from 8 microvolts to 100 microvolts across subjects, and at an intensity of 30 dB SL it ranged from 1 microvolt to 5 microvolts.

Figure 5 shows the fast evoked response recorded from the posterior wall of the cartilaginous portion in the external acoustic meatus as a function of click intensity. The configuration of the response is the same as that recorded from the post auricular region.

The whole nerve action potential response (AP) of the cochlear nerve appears simultaneously in the tracing (Figure 5). The AP was prominent at the osseous portion of the external acoustic meatus particularly near the tympanic membrane, whereas the fast evoked response identical with the post auricular response, was strongest at the cartilaginous portion of the external acoustic meatus, particularly at its posterior wall. Usually the amplitude of the fast evoked response was much larger than that of the AP. Moreover it showed a more rapid growth of amplitude as a function of click intensity in comparison with that of the AP as shown in Figures 3 and 5.

Figure 8 is a typical map of the post auricular response over the head in a normal subject. The largest response is recorded both from the limited area just behind the pinna and from the posterior wall of the cartilaginous portion in the meatus. It is distributed widely over the head attenuating its amplitude as a function of the distance between the electrode and the focus of the response. The source of the post auricular response may be localized to the post auricular region as pointed out by Johnson et al (1964). The response is detectable both from theinion and from the vertex but the amplitude is much reduced. In a few subjects a short latency response, identical with the post auricular response except for a prolonged latency was

Figure 5 Summed responses to clicks recorded from the external acoustic meatus in a young normal subject. Each trace is the summed waveform of responses to 500 clicks. The active electrode was placed at the posterior wall of the cartilaginous portion of the external acoustic meatus. Both the AP and the post auricular response (n , p , n_2) are seen each trace.

Figure 6 Summed post-auricular responses to clicks recorded from various electrode positions on the scalp. The subject, 31-year-old male with normal hearing, was seated in a chair holding his head in a natural upright position. The click intensity was 80 dB SL. Responses to 500 clicks were summed by the computer. The beginning on the left side of each trace indicates the arrival of the click and the start of the trace.

Figure 7 *Positive effect of muscular tension on the post auricular response to clicks.* The subject, a 17 year-old male with normal hearing was seated in a chair either flexing the head and neck forward (upper tracing) or holding the head in a natural upright position (lower tracing). Each tracing is the summed waveform of responses to 500 clicks. Marked amplification in magnitude of the response is seen in the upper tracing.

recorded from the arms and the legs.

These distributions of the post auricular response on the head are practically identical with those reported by Kiang et al (1963), and Jacobson et al (1964).

The post auricular response was a bilateral response to monaural acoustic stimuli. When the contralateral ear alone was stimulated by clicks through an earphone, the response could be recorded simultaneously on both sides in the post auricular regions.

Figure 7 illustrates a positive effect of muscular tension of the head and the neck on the magnitude of the response. Forward flexion of the neck was very effective for increasing the response. The amplitude was highly enhanced by holding down the head as low as possible. In general holding the head back well decreased the amplitude of the post auricular response, in comparison with holding the head naturally in an upright position. The degree of amplification of the amplitude in the forward flexion of the neck ranged from about 3 times to 10 times as large as that obtained in an upright position. When the subject lay in a supine position on a bed the use of a pillow resulted in an effect similar to that of forward flexion of the neck. These findings are in close agreement with those observed on the (inon

The active electrode was placed at the posterior wall of the cartilaginous portion of the external acoustic meatus. Both the AP and the post auricular response (n , p_1 , n_2) are seen each trace.

Figure 6. Summed post auricular responses to clicks recorded from various electrode positions on the scalp. The subject, 34-year-old male with normal hearing, was seated in a chair holding his head in natural upright position. The click intensity was 80 dB SL. Responses to 500 clicks were summed by the computer. The beginning (on the left side) of each trace indicates the arrival of the click and the start of the trace.

Figure 7 Positive effect of muscular tension on the post auricular response to clicks. The subject 17 year-old male, with normal hearing was seated in chair either flexing the head and neck forward (upper tracing) or holding the head in natural upright position (lower tracing). Each tracing is the summed waveform of responses to 500 click. Marked amplification in magnitude of the response is seen in the upper tracing.

recorded from the arms and the legs.

These distributions of the post auricular response on the head are practically identical with those reported by Kiang et al (1963), and Jacobson et al (1964).

The post auricular response was a bilateral response to monaural acoustic stimuli. When the unilateral ear alone was stimulated by clicks through an earphone, the response could be recorded simultaneously on both sides in the post auricular regions.

Figure 7 illustrates a positive effect of muscular tension of the head and the neck on the magnitude of the response. Forward flexion of the neck was very effective for increasing the response. The amplitude was highly enhanced by holding down the head as low as possible. In general holding the head back well decreased the amplitude of the post auricular response in comparison with holding the head naturally in an upright position. The degree of amplification of the amplitude in the forward flexion of the neck ranged from about 3 times to 10 times as large as that obtained in an upright position. When the subject lay in a supine position on a bed the use of a pillow resulted in an effect similar to that of forward flexion of the neck. These findings are in close agreement with those observed on the lion

Figure 8. Summed post auricular responses to paired clicks recorded from a normal hearing subject holding his head in a natural upright position. Responses to 200 clicks with an intensity of 75 dB SL were summed by the computer. The ordinate marks the arrival of the first clicks and the start of the trace. The later arrows indicate the onset of the second click at various intervals after the first clicks.

Figure 9. Recovery curve of amplitude (p_1 to n_a) of the post auricular response. Each point is the average of measurements of the percent recovery for 3 normal subjects. Responses to 200 clicks were summed by the computer. The active electrode was placed behind the pinna. The subject was seated in a chair holding his head in a natural upright position. The percent recovery is the ratio, expressed as percentage of the second response to that of the first response.

response (Bickford et al 1964), and on the short latency vertex and parietal response (Mast, 1963, 1965).

Figure 8 is an example of the post auricular responses to paired clicks of the same intensity in which the first click is separated from the second by a short interval. The paired clicks are presented at a long interval of 500 msec, independently of the short interval. The amplitude of the second response is gradually reduced as the short interval decreases.

Figure 9 is the mean recovery function determined on 3 normal subjects of the p_1 to n_2 peak amplitude of the second response in relation to that of the first response as a function of the short interval. The percentage of the amplitude of the second response to that of the first one is plotted on the ordinate. The recovery curve rises rapidly from a recovery level of about 20 per cent at the interval of 20 msec to a recovery level of 90 per cent at the interval of 100 msec, and then it increases very slowly towards a recovery level of 100 per cent. The short interval necessary for full recovery may approximate 200 msec. The time course of the recovery process of the post auricular response appeared to be much faster than that of the slow Vertex potential evoked response, but slower than that of the AP.

Finally we have recorded no response to intense clicks at intensities above 100 dB SPL (peak equivalent) from the post auricular region in patients who suffer from severe sensorineural hearing loss but with normal vestibular function. Strong flexion of the neck in a forward direction was not effective in evoking the response from these patients. This may be contradictory to the observations on theinion response (Bickford et al 1964; Cody et al 1964), but is compatible with those reported by Ruhn et al (1967).

DISCUSSION

Characteristics of the fast evoked responses recorded from the post auricular region and the external acoustic meatus

On the basis of the above observation it is clear that our responses are essentially identical with the post auricular response of Kiang et al (1963). The distribution of the response on the scalp is also in close agreement with that reported by Jacobson et al (1964). High sensitivity to acoustic stimuli may be a feature worthy of special mention in the post auricular response in contrast to the inion response which has a high threshold. Additional features are the ease of recording the response and its stability.

Clinical significance of the Fast Evoked responses

The hypothesis of a widespread sonomotor response system in man,

as first put forward by Bickford et al (1963 a b), has been generally accepted by many investigators (cf Cody et al 1964 Davis et al 1964 Davis 1965 Colesia et al 1968 Ruhm et al 1967 Borsanyi 1964 Borsanyi & Blanchard 1964). Recently an interesting explanation regarding the mechanisms and pathways of the fast evoked responses was offered by Ruhm et al (1967), namely that there may be a dual system operating in the same time domain comprising a cochleo neurogenic system which has a low threshold and a vestibulo myogenic system which has a high threshold. By extension of the dual organization theory of Ruhm et al (1967), it would be reasonable to speculate that the fast evoked response may be a mixed response consisting of (1) a cochleo myogenic response (2) a cochleo neurogenic response, and (3) a vestibulo myogenic response. But actually such a triple organization in man has not yet been demonstrated.

In the light of the experimental evidence collected by the authors, as mentioned earlier in the introduction the following inferences may be of interest (1) The major component of the post auricular response may be interpreted to be cochleo myogenic in origin (2) The inion response of Bickford et al (1964), and Cody et al (1964), may be vestibulo myogenic in origin (3) The short latency vertex and parietal response may be a composite response consisting of the cochleo neurogenic component (Mast, 1963 1965 Davis 1966 Goldstein 1965 Ruhm et al 1967), the cochleo myogenic component (Mast 1963 1964 Davis, 1966 Goldstein & Rodman 1967), and the vestibulo myogenic response (Ruhm et al 1967 Cerecia et al 1968).

As regards the cochleo neurogenic component of the fast evoked response Davis et al (1966), in support of the view of Mast (1963, 1965), have suggested that a small early neurogenic auditory response of a 30 msec peak latency might be detected in appropriate area in addition to the somomotor response but the overwhelming myogenic response made it very difficult to detect.

Audiometric use of the fast evoked responses

Among a group of fast evoked responses the inion response would not serve as an index of hearing estimation because of the vestibular mediation as described by Bickford et al (1964), and Cody et al (1964).

On the other hand as both the post auricular and the short latency vertex and parietal responses seem to be evoked by cochlear receptors they would be valid for objective audiometry. These responses have been proved not only to be relatively stable and consistent but also to have a low threshold according to Kiang et al (1963), Mast (1965), Borsanyi (1964), Ruhm et al (1967) Goldstein (1965), and Goldstein & Rodman (1967). Our findings on the post auricular response support the view of Goldstein & Rodman (1967) that audiometric use

of the fast evoked response, for "objective" measurement of hearing threshold in man may be promising.

As cited earlier Blackford et al (1964) have also pointed out the theoretical importance of the human somomotor response in differentiating vestibular disease.

Apart from threshold measurements, another point of interest is that the myogenic evoked potentials, irrespective of the receptors (vestibular or cochlear), may be of practical value in differential diagnosis of oto neurological diseases in the brain stem. Davis (1963) has already emphasized that the myogenic evoked potentials may serve to differentiate failure of response due to lesions of the brain stem from impairment of the cochlea or of the brain cortex.

As a matter of fact, in view of possible diagnosis of central perceptive deafness it is reasonable to accept this suggestion. Theoretically the myogenic evoked potentials may be applicable to differential diagnosis of auditory and vestibular diseases in the brain stem region but much remains to be determined as to the anatomical pathway and physiological function of the response.

ACKNOWLEDGEMENTS

We wish to express our gratitude to the Director of the Department of Otolaryngology Professor Tokuro Suzuki Shinshu University Matsumoto for his encouragement and generous support throughout the entire investigation.

We also wish to express our sincere thanks to Dr Hallowell Davis, Central Institute for the Deaf, St. Louis, Mo. for his stimulating discussions and constructive criticism and for his careful review of the manuscript.

We are greatly indebted to Professor Dr Ernst Lehnhardt, Universitätsklinik und Poliklinik für Hals, Nasen und Ohrenkrankheiten, Hamburg Eppendorf for his great help in making the German version of the manuscript.

ZUSAMMENFASSUNG

Nach Click Reizung wurden die myogenen evoked potentials beim Menschen sowohl am äußeren Gehörgang als auch intraurikulär mit Hilfe eines Mittelwertrechners registriert. Die Antworten zeigten sich als dreiphasische Welle und war als negativ positiv negativ. Welle mit einer extrem Latenz der Spitzen (10-15-25 msec). Der Herd dieser Antworten ist offenbar in einem unachsenbezogenen retroaurikulären Bezirk gelegen. Die Schwelle der Antworten war relativ konstant und niedrig. Durch Vorwärtsneigen des Kopfes ließen sich die Größe der Antworten erheblich steigern. Die postaurikulären Antworten werden interpretiert als cochleo-myogenen Ursprungs. Sie lassen sich gut für die objektive Audiometrie verwenden. Außerdem besteht grundsätzlich die Möglichkeit, dass die Antworten für elektrophysiologische Versuche verwendet werden können zur Differenzierung verschiedener otoneurologischer Störungen im Zusammenhang mit Schädigungen des Hirnstamms.

INTRODUCTION

It is generally agreed that "vestibular neuronitis" is an abnormality of the vestibular system without an accompanying auditory deficit. It is also generally agreed that vestibular neuronitis is frequently associated with an infectious process and that it tends to occur in relatively young adults. Beyond this, however, there is little agreement concerning the precise delineation of what constitutes "vestibular neuronitis."

Proponents of differing views tend to form two distinct groups. The first group accepts a rather broad definition of vestibular neuronitis, including either multiple or single attacks of vertigo or dizziness, and any type of abnormality disclosed by vestibular examination. The second group accepts a more limited concept of what comprises vestibular neuronitis, maintaining that there is only a single usually very severe, episode of vertigo, that the vestibular examination shows a unilateral weakness of the caloric responses, and that, if done early in the course of the illness, it also shows a spontaneous nystagmus directed away from the unilateral weakness. These investigators uniformly regard the entity as self-limiting, whereas those using the broader definition disagree about this point.

The condition was originally described by Dix and Hallpike in 1932. Their criteria provide an example of the broader definition, as they characterized the attacks of vertigo or dizziness as either multiple or single and reported that of their 100 cases, 47 had bilateral canal paresis and 53 had unilateral canal paresis. They also reported that the condition "generally ceases within a few years." The following investigators have also used the broad definition. Harrison (1962) studied 67 patients conforming to the original description by Dix and Hallpike and found that in 29 the attacks were repeated over periods up to 7 years. No spontaneous nystagmus was encountered in this series. Lumio and Aho (1965) studied 40 patients with "vestibular neuronitis," and found that of 27 patients followed for at least 6 months, all showed complete recovery or only mild, recurrent unsteadiness. Boffa (1965) reported on 83 cases with a diagnosis of vestibular neuronitis according to the definition of Dix and Hallpike. He postulated a relationship between vestibular neuronitis and paroxysmal positional nystagmus, which Lindsay (1967) also suggested. Lindsay preferred to reserve the term, "vestibular neuronitis," for patients with a "vestibular disturbance of inflammatory origin in which definite localizing signs are lacking."

The following investigators have applied the more restricted definition. Cawthorne (1964) stated that the condition is characterized by a "sudden and often complete loss of vestibular function on one side." Examination in

INTRODUCTION

It is generally agreed that "vestibular neuronitis" is an abnormality of the vestibular system without an accompanying auditory deficit. It is also generally agreed that vestibular neuronitis is frequently associated with an infectious process and that it tends to occur in relatively young adults. Beyond this, however, there is little agreement concerning the precise delineation of what constitutes "vestibular neuronitis."

Proponents of differing views tend to form two distinct groups. The first group accepts a rather broad definition of vestibular neuronitis, including either multiple or single attacks of vertigo or dizziness, and any type of abnormality disclosed by vestibular examination. The second group accepts a more limited concept of what comprises vestibular neuronitis, maintaining that there is only a single, usually very severe episode of vertigo, that the vestibular examination shows a unilateral weakness of the caloric responses, and that, if done early in the course of the illness, it also shows a spontaneous nystagmus directed away from the unilateral weakness. These investigators uniformly regard the entity as self-limiting, whereas those using the broader definition disagree about this point.

The condition was originally described by Dix and Hallpike in 1932. Their criteria provide an example of the broader definition, as they characterized the attacks of vertigo or dizziness as either multiple or single and reported that of their 100 cases, 47 had bilateral canal paresis and 53 had unilateral canal paresis. They also reported that the condition "generally ceases within a few years." The following investigators have also used the broad definition. Harrison (1982) studied 67 patients "conforming to the original description by Dix and Hallpike," and found that in 29 the attacks were repeated over periods up to 7 years. No spontaneous nystagmus was encountered in this series. Lumio and Aho (1985) studied 40 patients with "vestibular neuronitis," and found that of 27 patients followed for at least 6 months, all showed complete recovery or only mild, recurrent unsteadiness. Boffi (1985) reported on 11 cases with a diagnosis of vestibular neuronitis according to the definition of Dix and Hallpike. He postulated a relationship between vestibular neuronitis and paroxysmal positional nystagmus, which Lindsay (1967) also suggested. Lindsay preferred to reserve the term, "vestibular neuronitis," for patients with a "vestibular disturbance of inflammatory origin in which definite localizing signs are lacking."

The following investigators have applied the more restricted definition. Caathorne (1964) stated that the condition is characterized by a "sudden and often complete loss of vestibular function on one side." Examination in

the acute stage shows "a gross vestibular nystagmus. The quick component is directed towards the sound side. . . . At the end of three weeks the nystagmus has disappeared and equilibrium is more or less restored." Dolowitz (1905) characterized vestibular neuronitis as a sudden acute vestibular failure affecting all or part of the [peripheral vestibular apparatus]. This disease is characterized by an apparently normal person suddenly being seized with violent vertigo, nausea and vomiting any time that the head is moved. The only pathological signs are the decreased labyrinthine responses. [The disease] is self limiting. Lachman and Stahle (1961) studied 45 cases of vestibular neuronitis in the acute stage. In all cases the vertigo had a precipitous onset. The caloric test showed a [unilateral] canal paresis in all cases and a vigorous spontaneous nystagmus away from the canal paresis. The disease was characterized as having a 'protracted course from weeks to months.

Hart (1965) recognized within the original broadly defined syndrome an entity essentially identical to that of the more restricted definition but preferred to call it "vestibular paralysis of sudden onset and probable viral etiology. He reserved the term 'vestibular neuronitis' for all other cases of vestibular derangement without associated auditory deficit. Of particular importance is Hart's suggestion that whether single or multiple episodes of vertigo are present represents an important criterion for subdividing the syndrome of vestibular neuronitis as originally described by Dix and Hallpike.

It is noteworthy that investigators utilizing the electronystagmographic (ENG) examination to provide diagnostic criteria tend to adopt the more restricted definition. The ENG examination thus may provide worthwhile information not given by other diagnostic procedures.

The present study was undertaken in an attempt to clarify the confusion surrounding the definition of vestibular neuronitis by establishing precise and limiting diagnostic criteria for the entity. A group of patients fulfilling these criteria were then analyzed to determine the significance of other clinical findings in the group.

SECTION I DEFINITION OF VESTIBULAR NEURONITIS

MATERIALS AND METHODS

We approached the problem of defining the vestibular neuronitis in the following way. First, we tried to determine whether various characteristics supposed to typify the entity were significantly more prevalent among patients with a vestibular deficit but without an auditory deficit than among control patients (i.e. those with both a vestibular and an auditory deficit, and those with normal auditory and vestibular function). Second, we studied the group of patients with a vestibular deficit and normal hearing to determine whether it was completely homogeneous or whether it could be divided into subgroups of patients with and without vestibular neuronitis. We subdivided the group into patients with single and patients with multiple episodes of vertigo to see whether the various characteristics supposedly typical of vestibular neuronitis were significantly more prevalent in one of the subgroups than in the other. Single- and multiple-episode subgroups of the control groups were also compared to rule out the possibility that differences between the study subgroups were due solely to the presence of single episodes of dizziness in one subgroup and multiple episodes in the other.

The patients studied were obtained from 1346 consecutive patients referred to the electronystagmographic laboratory at The Methodist Hospital in Houston, Texas.

To be included in the study it was required that a patient complain of dizziness, defined as something equivalent to giddiness or light headedness as well as a spinning sensation, and also that he meet the criteria of one of the three study groups, defined below. A total of 604 patients fulfilled these criteria.

Control group 1 Normal

Included in this group were 418 patients with caloric unilateral weakness and directional-preponderance measurements of less than 20% without spontaneous or positional nystagmus, and without optokinetic asymmetry or gaze nystagmus.

Control group 2 Caloric unilateral weakness with correlated auditory deficit (auditory and vestibular or "A & V")

The 110 patients in this group had unilateral-weakness measurements of 20% or more and had a hearing loss, by history on the same side or when

audiogram was available (94 patients) had a difference in hearing level of at least 20 db (averaged over the 500-2000 Hz range)

Study group Caloric unilateral weakness without significant hearing loss (vestibular-only or V-only)

The 76 patients in this group had unilateral weakness measurements of 20% or more and had normal hearing by history or when an audiogram was available (36 patients) had an average hearing level over the 500-2000 Hz range of 20 db or less in both ears

All of the 604 patients were given an ENG examination which consisted of a test for gaze nystagmus with eye deviation quantitated at 20° from the midline, an optokinetic test, a position test according to Aschan *et al* (1956) modification of Nylén's technique, and a Fitzgerald Hallpike (1942) caloric test.¹ The caloric responses were quantitated by measuring maximum eye speed. Directional preponderance (DP) and unilateral weakness (UW) were expressed as a percentage of the total of all four caloric responses. "Limit of normal" (determined by doubling the standard deviation obtained from a series of normal subjects) was 20% for both UW and DP. Additional details of the test procedure are published elsewhere (Coats, 1965, 1966).

A complete otoneurologic history was obtained from all of the patients. In addition a vigorous effort was made to obtain records from referring physicians, from hospitals (if the patient was an inpatient at the time of the examination) and of test results pertinent to the otoneurologic examination particularly of audiometric examinations.

RESULTS

Comparison between the V-only group and the two control groups

Multiple and single episodes of vertigo For this study a single episode of vertigo was defined as one or a series of attacks occurring within a 10-day period. Episodes not fitting this definition were regarded as multiple. In Fig. 1 are plotted the incidences of single and multiple episodes in the three groups.

It is apparent that the incidence of single episodes is much higher in the V-only group than in either of the control groups. This difference is statistically significant (see Appendix I). However in the V-only group, multiple episodes outnumbered single episodes. Similar observations have undoubtedly led others to conclude that "vestibular neuronitis" may be manifested by either multiple or single episodes of dizziness.

Age distribution Distributions of patients' ages in the three groups are shown in Fig. 2. It is apparent that patients with V-only deficit tended to be

W. H. R. received to set temperature of 31°C and 43°C (irrigation) and 40 second) with the 30°C and 44°C. W. find that this method of reducing stimulation intensity is better than shortening the duration of the irrigation (Aschan *et al* 1956). been as shortening the duration of the irrigation as the stability of the response.

Fig. 1

Fig. 1 Percentages of patients in the three groups complaining of multiple and single episodes of dizziness.

Fig. 2 Age distribution in the three patient groups.

Fig. 2

younger than patients in the control groups. This difference is highly significant (see Appendix, II). There was no significant age difference between the two control groups.

Incidence of antecedent infection (Table 1) The incidence of infection during the two months prior to the ENG examination was as follows (Fig. 3) (1) in the V-only group, 29 of 8 patients (36.2%) (2) in the A & V

Fig. 3 Percentages of patients in the three groups with history of infection within two months prior to the ENG examination.

Flu	5	1.3	0	0	1	1.1	0	0	1	2.1	2	6.9
Specific viral	3	0.8	0	0	7	7.7	2	10.5	1	2.1	1	3.4
Other	8	2.0	1	3.7	1	1.1	1	5.3	1	2.1	4	13.8
Total	39	10.0	3	11.1	13	14.3	7	36.8	16	34.0	13	44.8

Definitions

Upper respiratory—"cold and/or "sore throat

Sinusitis— sinusitis or sinus congestion diagnosed by referring physician.

Middle ear—symptom and/or signs of chronic or acute middle-ear infection which had been active within two months of examination

Flu—febrile illness, usually associated with upper respiratory infection which could not be classified as a specific viral infection

Specific viral—measles, mumps, chicken pox, herpes zoster and "meningoencephalitis

Other—a wide variety of types which could not be classified according to the above criteria. Most infections by bacterial or other non-viral organisms were included in this category

group 20 of 110 patients (18.2%) and (3) in the normal group 42 of 418 patients (10.1%). The incidence in the V-only group was significantly higher than that of the control groups (see Appendix III). The incidence in the A & V group was significantly higher than in the normal group. This difference was largely attributable to higher percentages of patients with middle-ear and specific viral infections in the A & V group.

Other etiological factors. Other etiological factors were studied in an attempt to demonstrate a significantly higher concentration in the V-only group in comparison with the control groups. However none of the possibilities studied (diabetes, head trauma, vascular insufficiency, streptomycin intoxication, barotrauma, and bleeding episodes) occurred significantly more often in the V-only group. This negative result does not exclude the possibility that a significant positive result might be produced by study of a larger population.

Incidence of spontaneous nystagmus. Of the 76 V-only patients, 61 (40 patients) had spontaneous nystagmus. Only 44% (49 patients) of the 110 A & V patients had spontaneous nystagmus. This difference is statistically significant (see Appendix IV). As will be shown the high incidence of spontaneous nystagmus among the V-only patients is attributable entirely to

the high incidence of spontaneous nystagmus among patients with single episodes of dizziness.

Conclusion A group of patients with a vestibular deficit but without a corresponding auditory deficit differed significantly in several respects from a group of normal patients and from a group of patients with both vestibular and auditory deficits. The V-only patients tended to be younger, had a higher incidence of antecedent infections and spontaneous nystagmus, and more of them complained of only a single episode of dizziness. These findings suggest that the V-only group contained a high concentration of a particular entity (vestibular neuritis) which has these characteristics. However, these findings by no means prove that the V-only group contained only this entity. If the V-only group could be subdivided according to some predetermined criterion, and the subgroups shown to differ significantly in one or more respects, then it would seem doubtful that patients with a vestibular deficit, but without an auditory deficit, constitute a homogeneous group. As shown in the following section, V-only patients with only a single episode of dizziness differed significantly in several respects from V-only patients with multiple episodes of dizziness.

Comparison of multiple- and single-attack subgroups

Age distribution. In Fig. 4 are shown the age distributions in the six subgroups formed by subdividing the three major groups according to whether their attacks of dizziness were multiple or single. The V-only-single-attack subgroup was the youngest, with a modal age of 30-39. The V-only multiple-attack subgroup was significantly older than the V-only single-attack subgroup, and did not differ significantly in age from the control subgroups (see Appendix, II). In contrast to the V-only group, there were no significant age differences between subdivisions of the control groups.

Amount of unilateral weakness. In Fig. 5 are shown frequency distribution of amount of unilateral weakness in subgroups of the two groups with unilateral weakness. The UW measurements in the V-only multiple-attack subgroup show a strikingly high percentage at the low end of the scale when compared with the UW measurements in the other three subgroups. This difference is highly significant (see Appendix, I). There are no significant differences among the other three subgroups. Thus patients in the V-only multiple-attack subgroup tend to have significantly smaller UW measurement than patients in the other subgroups.

Incidence, intensity, and direction of spontaneous nystagmus. The incidence of spontaneous nystagmus (nystagmus present with the patient supine and eyes closed) in subgroups of the two UW groups is shown in Fig. 6. The incidence is highest in the V-only-single-attack subgroup (80%). In Fig. 7 the spontaneous nystagmus has been categorized according to intensity and direction relative to the weak side. The V-only-single-attack subgroup differs in that in all instances where spontaneous nystagmus was present it was directed away from the side of the unilateral weakness, and in the majority

Table 1 Antecedent infection in patient groups

Type of Infection	Normal				A & V				V-only

Definitions

Upper respiratory—"cold" and/or "sore throat"

Sinusitis=sinusitis or sinus congestion diagnosed by referring physician.

Middle ear=symptoms and/or signs of chronic or acute middle-ear infection which had been active within two months of examination.

Flu=febrile illness, usually associated with upper respiratory infection which could not be classified as a specific viral infection.

Specific viral=measles, mumps, chicken pox, herpes zoster and "meningoencephalitis."

Other=a wide variety of types which could not be classified according to the above criteria; most infections by bacterial or other non-viral organisms were included in this category.

group 20 of 110 patients (18.2%) and (3) in the normal group, 42 of 418 patients (10.1%). The incidence in the V-only group was significantly higher than that of the control groups (see Appendix, III). The incidence in the A & V group was significantly higher than in the normal group. This difference was largely attributable to higher percentages of patients with middle-ear and specific viral infections in the A & V group.

Other etiological factors Other etiological factors were studied in an attempt to demonstrate a significantly higher concentration in the V-only group in comparison with the control groups. However, none of the possibilities studied (diabetes, head trauma, vascular insufficiency, streptomycin intoxication, barotrauma, and bleeding episodes) occurred significantly more often in the V-only group. This negative result does not exclude the possibility that a significant positive result might be produced by study of a larger population.

Incidence of spontaneous nystagmus Of the 76 V-only patients, 61 (46 patients) had spontaneous nystagmus. Only 44 (48 patients) of the 110 A & V patients had spontaneous nystagmus. This difference is statistically significant (see Appendix IV). As will be shown, the high incidence of spontaneous nystagmus among the V-only patients is attributable entirely to

Fig. 7 Percentage distributions of intensity of spontaneous nystagmus and direction relative to side of UV. Spontaneous-nystagmus intensity measurement were categorized as low 0.1-6.9 sec; moderate 6.9-9.9 sec; high 10.0 sec+.

subgroups are significant. This is largely attributable to the relatively high incidence (19.1%) of sinusitis in the V-only multiple-attack subgroup (Fig 8). It was required that sinusitis or "sinus congestion" have been diagnosed by the referring physician before the patient was considered to have this disorder.

In contrast to the V-only multiple-attack subgroup all types of infection occurred with approximately equal frequency in the V-only single-attack subgroup. The highest incidence was in the "other" category. The four patients in this category had the following types of infection: positive serology with probable asymptomatic tertiary syphilis, jaundice and fever of unknown origin, colitis with diarrhea and fever and bronchitis with fever.

Follow-up study. Thirty-six V-only patients with UV measurements of 30% or more and with antecedent infection, were contacted 1 to 4 years after the ENG examination. Of these, 20 had only a single episode of dizziness. These patients meet the definition of vestibular neuronitis proposed below. The remaining 16 patients had multiple episodes of dizziness. According to many investigators, these patients also have vestibular neuronitis (they have a vestibular deficit, normal auditory function, and an antecedent infection). However as proposed below they should be excluded because they had multiple attacks of dizziness.

A short questionnaire was mailed to each patient. The patient was asked whether there had been recurrent dizziness. If so, he was asked to grade the recurrence as "more severe," about as severe, "less severe" or much less severe than the episode occurring at the time of the examination. Also, he was asked whether medical treatment had been sought for recurrent dizziness. In addition, the questionnaire provided space for comments.

Of the 36 patients, 26 returned the questionnaire. Eight additional patients were interviewed by telephone. Two patients were lost to follow-up; one

of instances, was of moderate or high intensity. These differences are statistically significant (see Appendix IV).

Incidence and type of infection When infection was subdivided according to type, a significant difference between the V only multiple-attack and V only single attack subgroups was found. In Table 1 the incidence of different types of infection in the six subgroups is shown. Although the overall incidences of infection in the V-only multiple attack and V-only single-attack subgroups (34.0% and 44.8% respectively) do not differ significantly (see Appendix III) differences between the types of infection in these two

Fig 6 Percentages of patients with spontaneous attacks in the two subgroups.

"much less severe" dizziness in this group. Thus, one patient related a single "much less severe, recurrent episode occurring after she had attended a wedding with a large crowd following lack of sleep the night before." Another patient related a single episode, and stated, "I am sure it was from overwork and no time for eating." A third patient stated that he "gets dizzy" if he goes too fast or stands too long.

In contrast to the single-attack subgroup, none of the patients with multiple attacks offered comments which specifically related recurrent episodes of dizziness to fatigue, emotional stress, or drug ingestion. The only specific cause of recurrent dizziness volunteered by patients in this group was given by two patients who related their recurrent attacks to exacerbations of sinusitis.

DISCUSSION

Differences between the V-only group and the control groups

The results of this study indicate that patients with caloric unilateral weakness without associated hearing deficit (V-only patients) differ significantly from control groups in that (1) they tend to be younger, (2) they tend to present with only a single episode of dizziness, (3) they have a relatively high incidence of spontaneous nystagmus, and (4) they have associated infection with much greater frequency.

These results support the definition of "vestibular neuronitis" as an entity which is characterized by a vestibular deficit without auditory deficit, usually occurring in a relatively young adult who frequently gives a history of antecedent infection. That the definition should include the stipulation that there be only a single attack of dizziness is indicated by the additional results discussed below.

Differences between the V-only multiple-attack and V-only single-attack subgroups

The V-only group with multiple attacks of dizziness differed significantly in several respects from the V-only group with a single attack. The severity of caloric unilateral weakness in the V-only-multiple-attack group tended to be much less than in the single-attack group. Also, patients with multiple attacks tended to be older than patients with single attacks (though still younger than the control groups). This is in contrast to the control groups, where patients with multiple and single attacks showed no significant age difference. Also, a follow up study showed a much higher incidence of relatively severe recurrent episodes in the multiple-attack group as compared to the single-attack group. Finally, patients with multiple attacks showed a striking tendency to have sinusitis. No such tendency was found in any of the other patient groups. The high incidence of sinusitis among V-only patients with multiple attacks suggests that at least one separate disease entity occurs within this subgroup.

Fig. 8

Fig. 9

Fig. 8 Percentages of patients in the six subgroups with abnormality within two months prior to the ENG examination (diagnosed by referring physician)

Fig. 9 Recurrent episodes of dizziness in patients on whom follow-up information was obtained. Solid bars represent patients seeking medical care for recurrent attacks. Cross-hatched bars represent patients with recurrent attacks but not seeking medical care. The upper plot was obtained from the follow-up group meeting the definition of vestibular neuronitis proposed in this report (caloric unilateral weakness without auditory deficit with single recent episode of dizziness, and with antecedent infection). The lower plot was obtained from a group of patients with the same characteristics except that they presented with a history of multiple episodes of dizziness. None=no recurrent dizziness. MLS=recurrent episode(s) much less severe than initial episode. LS=less severe recurrent episode(s). AS=a severe recurrent episode(s); MS=more severe recurrent episode(s).

with multiple attacks had died of a myocardial infarction two months after the ENG examination.

The results of the follow-up study are presented in Fig. 9. It is apparent that patients with only a single attack of dizziness at the time of the ENG examination were relatively free of subsequent attacks. In contrast, most patients who had had multiple attacks at the time of the ENG examination continued to have relatively severe attacks after the examination.

The "comments" which were volunteered by many of the patients provide some interesting insights into probable causes of the recurrent episodes of dizziness and also into differences between the multiple- and single-attack subgroups. It is easy to visualize occasional episodes of mild dizziness occurring in a patient with a stable peripheral vestibular deficit caused not by exacerbation of the peripheral lesion but by a temporary unbalancing of the central compensation for the peripheral lesion. Fatigue, emotional stress, or drug ingestion (e.g., alcohol, sedatives) would be expected to produce such a temporary "decompensation." Several of the comments volunteered by patients in the single-attack follow-up group support the view that this mechanism accounted for many of the recurrent episodes of

patients meeting our proposed definition of vestibular neuronitis. The results of the present study thus suggest that an isolated vestibular deficit associated with sinusitis represents an entity which is distinct from "vestibular neuronitis." The comments volunteered by two of the follow up patients that recurrent episodes of dizziness were associated with exacerbation of their sinusitis are further evidence for this view.

Etiologic factors in vestibular neuronitis

It is frequently suggested that vestibular neuronitis may be caused by viral infection. In the present survey a significant relationship between infection and vestibular neuronitis was found, but there was no association with a specific type of infection. Therefore in vestibular neuronitis, infection is probably a secondary rather than a primary etiologic factor.

SUMMARY OF SECTION I

A group of 76 patients with peripheral vestibular deficits and normal hearing differed significantly from 528 "control" patients in the following areas: (1) younger median age (30-40 vs. 50-60) (2) higher incidence of antecedent infection, (3) higher incidence of spontaneous nystagmus, and (4) greater percentage of patients with only a single attack of dizziness. Among the 76 patients, those with single attacks of dizziness differed significantly from those with multiple attacks in a number of ways. Therefore, it is suggested that the definition of vestibular neuronitis include the stipulation that there be only a single attack of dizziness. A follow up study showed that recurrent dizziness was rare in patients presenting with only a single episode but was common in patients presenting with multiple episodes. Among patients with multiple episodes, a possibly new entity "isolated vestibular deficit associated with sinusitis," was found. On follow up, two of these patients voluntarily commented that recurrent episodes of dizziness were associated with exacerbations of their sinusitis.

Another possible explanation for the significant difference between the V-only multiple-attack and V-only single-attack subgroups must be considered. It can be argued that the marked tendency for the UW measurements in the V-only multiple-attack subgroup to cluster near the lower limit of the "pathological" range occurs because many of these measurements are in fact spuriously abnormal results. It will be recalled that the 20% limit of normal is determined by doubling the standard deviation obtained from a population of normal subjects. Thus, by definition, about 4.5% of normal individuals will fall outside this "limit of normal." Most of the patients with normal ENC's complained of multiple attacks of dizziness. Also, the V-only group by definition constitutes patients with supposedly peripheral vestibular deficits unconfirmed by auditory deficits. Therefore it would be expected that the spuriously "abnormal" caloric test results would tend to concentrate in the V-only multiple-attack subgroup.

This consideration constitutes another argument for excluding V-only patients with multiple attacks of dizziness from the same diagnostic classification as V-only single-attack patients. (It is also a strong argument for repeating the caloric test in such patients.)

It is apparent from these results that the V-only single-attack subgroup is relatively homogeneous, being largely made up of patients with what we propose be called vestibular neuronitis. The V-only multiple attack subgroup is a conglomerate of at least two entities: (1) spuriously "abnormal" unilateral weakness measurements, and (2) a possibly new entity vestibular deficit associated with sinusitis. The results of this study thus indicate that the definition of "vestibular neuronitis" should include the stipulation that the patient have had only a single attack of dizziness. This stipulation may or may not exclude a few "atypical" examples, but in addition to fitting the data presented here it gives the diagnosis prognostic value.

Vestibular deficit associated with sinusitis

A high incidence of sinusitis in patients with vestibular deficit and normal hearing has been reported by several investigators. In the series of Dix and Hallpike (1952) otitis media was the most frequent type of infection. Hinchcliffe (1964) stated that 70 to 80% of patients with vestibular neuronitis have roentgenographic evidence of sinusitis. Harrison (1962) reported that 9 of 67 patients with vestibular neuronitis (defined according to Dix and Hallpike) had evidence of otitis media. Pfaltz (1955) reported sinusitis in 17 of 25 cases with vestibular neuronitis (defined according to Dix and Hallpike). Lumio and Aho (1965) reported sinusitis in 10 of 40 patients with vestibular neuronitis.

In none of these studies was the relative incidence of sinusitis in patients with multiple and single attacks of dizziness compared. The present study shows a much higher incidence of sinusitis in patients with multiple attacks. Furthermore the follow up study indicates that the prognosis of an isolated vestibular deficit associated with sinusitis is poorer than the prognosis of

patients meeting our proposed definition of vestibular neuritis. The results of the present study thus suggest that an isolated vestibular deficit associated with sinusitis represents an entity which is distinct from "vestibular neuritis. The comments volunteered by two of the follow up patients that recurrent episodes of dizziness were associated with exacerbation of their sinusitis are further evidence for this view

Etiologic factors in vestibular neuritis

It is frequently suggested that vestibular neuritis may be caused by viral infection. In the present survey a significant relationship between infection and vestibular neuritis was found, but there was no association with a specific type of infection. Therefore in vestibular neuritis, infection is probably a secondary rather than a primary etiologic factor

SUMMARY OF SECTION I

A group of 76 patients with peripheral vestibular deficits and normal hearing differed significantly from 528 "control" patients in the following areas (1) younger median age (30-40 vs. 50-60) (2) higher incidence of antecedent infection, (3) higher incidence of spontaneous nystagmus, and (4) greater percentage of patients with only a single attack of dizziness. Among the 76 patients, those with single attacks of dizziness differed significantly from those with multiple attacks in a number of ways therefore, it is suggested that the definition of vestibular neuritis include the stipulation that there be only a single attack of dizziness. A follow-up study showed that recurrent dizziness was rare in patients presenting with only a single episode, but was common in patients presenting with multiple episodes. Among patients with multiple episodes, a possibly new entity: "isolated vestibular deficit associated with sinusitis," was found. On follow up two of these patients voluntarily commented that recurrent episodes of dizziness were associated with exacerbations of their sinusitis.

Another possible explanation for the significant difference between the V-only multiple-attack and V-only single-attack subgroups must be considered. It can be argued that the marked tendency for the UW measurements in the V-only multiple-attack subgroup to cluster near the lower limit of the "pathological" range occurs because many of these measurements are in fact spuriously abnormal results. It will be recalled that the 20% "limit of normal" is determined by doubling the standard deviation obtained from a population of normal subjects. Thus, by definition about 4.5% of normal individuals will fall outside this "limit of normal." Most of the patients with normal ENG's complained of multiple attacks of dizziness. Also, the V-only group by definition constitutes patients with supposedly peripheral vestibular deficits unconfirmed by auditory deficits. Therefore it would be expected that the spuriously "abnormal" caloric test results would tend to concentrate in the V-only multiple-attack subgroup.

This consideration constitutes another argument for excluding V-only patients with multiple attacks of dizziness from the same diagnostic classification as V-only single-attack patients. (It is also a strong argument for repeating the caloric test in such patients.)

It is apparent from these results that the V-only single-attack subgroup is relatively homogeneous, being largely made up of patients with what we propose be called vestibular neuronitis. The V-only multiple-attack subgroup is a conglomerate of at least two entities: (1) spuriously "abnormal" unilateral weakness measurements, and (2) a possibly new entity, vestibular deficit associated with sinusitis. The results of this study thus indicate that the definition of vestibular neuronitis should include the stipulation that the patient have had only a single attack of dizziness. This stipulation may or may not exclude a few "atypical" examples, but in addition to fitting the data presented here it gives the diagnosis prognostic value.

Vestibular deficit associated with sinusitis

A high incidence of sinusitis in patients with vestibular deficit and normal hearing has been reported by several investigators. In the series of Dix and Hallpike (1932) antral infection was the most frequent type of infection. Hinchcliffe (1964) stated that 30 to 50% of patients with vestibular neuronitis have roentgenographic evidence of sinusitis. Harrison (1962) reported that 9 of 67 patients with vestibular neuronitis (defined according to Dix and Hallpike) had evidence of antral infection. Pfaltz (1966) reported sinusitis in 13 of 25 cases with vestibular neuronitis (defined according to Dix and Hallpike). Lumio and Aho (1965) reported sinusitis in 3 of 40 patients with vestibular neuronitis.

In none of these studies was the relative incidence of sinusitis in patients with multiple and single attacks of dizziness compared. The present study shows a much higher incidence of sinusitis in patients with multiple attacks. Furthermore the follow up study indicates that the prognosis of an isolated vestibular deficit associated with sinusitis is poorer than the prognosis of

Table 2. Tinnitus and fullness in normal and vestibular neuronitis groups

	Tinnitus				Fullness			
	Normal		Vestibular neuronitis		Normal		Vestibular neuronitis	
	No.	%	No.	%	No.	%	No.	%
Limited to one ear	31	11.4	8	17.4	24	11.4	3	6.5
Bilateral or nonlocalizable	72	24.3	13	28.2	37	17.5	6	13.0
Same	191	64.3	25	54.3	236	87.5	51	80.4
Total	297		46		297		46	

vestibular neuronitis is compared with the incidence among 297 consecutively examined normal patients (with normal ENG's and normal audiograms). Slightly higher percentages of both bilateral and unilateral tinnitus occurred among the vestibular neuronitis patients. However this difference is not statistically significant (see Appendix, VI). There was also no significant difference in incidence of fullness between the normal and vestibular neuronitis groups.

Of the 8 vestibular neuronitis patients with unilateral tinnitus, 6 complained of tinnitus on the side of the vestibular deficit and 2 complained of tinnitus on the opposite side. This is suggestive, but would be expected to occur as a result of chance about 3 times out of 20, and therefore also cannot be considered significant.

Thus, although we have encountered suggestive complaints of tinnitus and fullness in patients with vestibular neuronitis, these cannot be shown to differ significantly from the complaints that would be expected from a group of patients not suffering from any identifiable auditory or vestibular disorder.

Rapidity of onset

The onset of vestibular neuronitis is frequently described as extremely rapid: a perfectly normal patient is struck down by a devastating attack of vertigo which renders him completely immobile. In our experience the onset of vestibular neuronitis, while more sudden than usually encountered in vestibular disorders, is not this rapid. The patients frequently complain of a prodromal period which may last from hours to days. During this period, there is a distinct feeling of "light-headedness" or being off balance. In some instances, the prodrome may be sufficiently severe that the patient goes to bed. The typical onset of vestibular neuronitis is demonstrated by the three cases presented below.

Associated changes in taste

In 2 of the 46 patients, there were distinct changes in taste on the same side of the tongue as the side of the vestibular deficit. One patient noticed

SECTION II OTHER CHARACTERISTICS OF VESTIBULAR NEURONITIS

In this section we will discuss those characteristics of vestibular neuronitis which either are not unique to the entity and therefore should not be included in the definition or which require narrative description and therefore do not lend themselves to the type of statistical analysis used in Section I

MATERIAL

A study of 46 patients with vestibular neuronitis, defined as proposed in the preceding section, is presented. Thirty were included in the population analyzed in Section I. An additional 16 patients were added from subsequent clinical material.

RESULTS

Sex incidence

Of the 46 patients with vestibular neuronitis, 20 were male and 26 were female. In a series of 45 patients with comparable clinical patterns, Lachman and Stahle (1967) reported that 21 were male and 18 were female. In a series of 40 vestibular neuronitis cases reported by Lumio and Aho (1965) (less comparable to ours since two patients had directional preponderance) 18 were male and 24 were female. In none of these series was one sex significantly (at the .05 level) predominant over the other. It is therefore concluded that vestibular neuronitis shows no significant preference for either sex.

Complaints of tinnitus and fullness

It has been reported that not only is hearing normal in vestibular neuronitis, but there is also a total absence of any complaint referable to the auditory system. We have been unable to confirm this. Although, by definition none of the 46 patients had a significant hearing loss, several complained of tinnitus and/or fullness in either one or both ears, often associated with the onset of vertigo (cf. cases 1 and 2). However, individuals with no identifiable auditory or vestibular pathology also often complain of tinnitus and fullness. Therefore, before these complaints can be considered significant among patients with vestibular neuronitis, they must be compared with the incidence among "normal" patients.

In Table 2 the incidence of tinnitus and fullness in the 46 patients with

Table II. *Tinnitus and fullness in normal and vestibular neuritis groups*

	Tinnitus				Fullness			
	Normal		Vestibular neuritis		Normal		Vestibular neuritis	
	No.	%	No.	%	No.	%	No.	%
Localized to one ear	34	11.4	8	17.4	24	11.4	3	6.5
Bilateral or nonlocalizable	72	24.3	18	38.3	37	12.5	6	13.0
None	191	64.3	25	54.3	236	87.5	37	80.4
Total	297		46		297		46	

vestibular neuritis is compared with the incidence among 297 consecutively examined normal patients (with normal ENG's and normal audiograms). Slightly higher percentages of both bilateral and unilateral tinnitus occurred among the vestibular neuritis patients. However this difference is not statistically significant (see Appendix, VI). There was also no significant difference in incidence of fullness between the normal and vestibular neuritis groups.

Of the 8 vestibular neuritis patients with unilateral tinnitus, 6 complained of tinnitus on the side of the vestibular deficit and 2 complained of tinnitus on the opposite side. This is suggestive but would be expected to occur as a result of chance about 3 times out of 20, and therefore also cannot be considered significant.

Thus, although we have encountered suggestive complaints of tinnitus and fullness in patients with vestibular neuritis, these cannot be shown to differ significantly from the complaints that would be expected from a group of patients not suffering from any identifiable auditory or vestibular disorder.

Rapidity of onset

The onset of vestibular neuritis is frequently described as extremely rapid—a perfectly normal patient is struck down by a devastating attack of vertigo which renders him completely immobile. In our experience, the onset of vestibular neuritis, while more sudden than usually encountered in vestibular disorders, is not this rapid. The patients frequently complain of a prodromal period which may last from hours to days. During this period, there is a distinct feeling of "light headedness" or being "off balance." In some instances, the prodrome may be sufficiently severe that the patient goes to bed. The typical onset of vestibular neuritis is demonstrated by the three cases presented below.

Associated changes in taste

In 2 of the 46 patients, there were distinct changes in taste on the same side of the tongue as the side of the vestibular deficit. One patient noticed

a loss of taste function on the involved side coincident with the onset of vertigo, and electrotaste testing confirmed reduced function. The other patient (case 2) complained of a metallic taste on the involved side. It thus appears that the (inflammatory?) process which presumably involves the vestibular nerve (see below) may also sometimes involve the chorda tympani.

Caloric responses

In their original description of vestibular neuronitis, Dix and Hallpike (1952) reported absent galvanic responses. Since the galvanic stimulus supposedly acts at a point central to the end organ this was thought to indicate involvement of the vestibular nerve rather than the end organ; therefore they proposed the term "vestibular neuronitis." To the knowledge of the author the absence of galvanic responses in vestibular neuronitis has not been independently confirmed.

We have found that the body sway response to galvanic stimulation, which consists of sway toward the positive electrode (applied to the mastoid area) and away from the negative electrode occurs with much lower stimulus levels than the nystagmic response (Coats, 1968). Because of this lower threshold body sway responses to unilateral stimulation are always easily obtained. In contrast the nystagmic response to unilateral stimulation can not be obtained because it requires painful current levels.

By recording the body sway response to galvanic stimulation a quantitative evaluation of unilateral galvanic responses can be obtained. The amplitudes of the four galvanic responses (right - left - right + left +) to monauricular monopolar stimulation are measured and galvanic directional preponderance and unilateral weakness are computed as with the four caloric responses.

Body sway galvanic tests in two patients with vestibular neuronitis have been obtained. One is presented as case 3. In both patients, a galvanic unilateral weakness on the side of the caloric weakness was present. Thus, our results support those of Dix and Hallpike and suggest that the lesion producing "vestibular neuronitis" does, indeed involve the vestibular nerve.

CASE REPORTS

The following three cases are representative of the entity vestibular neuronitis, defined as proposed in Section I.

Case 1

This 41 year-old Caucasian housewife with a chief complaint of dizziness, had been in excellent health until one morning 20 days before the ENT examination when she felt vaguely dizzy and nauseated with no definite sensation of vertiginous spin. She performed her normal morning activities, but in the afternoon she felt so ill that she went to bed and remained there for

Fig 10 Audiometric examination, Case 1

three days. During this time, she felt quite well as long as she lay quietly but the sensation of seasickness would return when she arose and she vomited once or twice when attempting this. After three days, she felt completely well, but five days later (12 days before the ENG) the difficulty returned, now with a definite sensation of spinning to her right. The severe vertigo persisted for three days, with several episodes of nausea and vomiting, then gradually subsided. At the time of the ENG examination, she complained only of a slightly off-balance sensation, but the vertigo would return with rapid head movement.

During her illness, the patient noted a roaring tinnitus somewhere in my head. This could not be lateralized to either ear.

About a week before the initial episode of dizziness, the patient had had an unusually severe cold, consisting of a stuffy nose and sore throat. She did not notice fever. There was no history of ototoxic-drug intake.

Results of examination of her ears, nose and throat, and a complete neurological examination on the day before the ENG examination showed no nystagmus and were otherwise entirely normal except for a tendency to sway to either side in tandem stance. Roentgenograms of the skull were normal. Audiometric-examination results (Fig. 10) also were normal. The ENG examination showed a moderately intense left-beating spontaneous nystagmus (Fig. 11) and an almost complete absence of caloric responses from the right labyrinth (Fig. 12).

Three months after the ENG examination, the patient was followed up by telephone. She had experienced some residual unsteadiness for about a month after the examination, but since then had remained entirely symptom-free.

Comment. This is a typical example of vestibular neuronitis. The history well illustrates that the onset of the vertigo is usually not "sudden" or "precipitous" as it is sometimes described.

a loss of taste function on the involved side coincident with the onset of vertigo, and electrostatic testing confirmed reduced function. The other patient (case 2) complained of a metallic taste on the involved side. It thus appears that the (inflammatory?) process which presumably involves the vestibular nerve (see below) may also sometimes involve the chorda tympani.

Galvanic responses

In their original description of vestibular neuronitis, Dix and Hallpike (1952) reported absent galvanic responses. Since the galvanic stimulus supposedly acts at a point central to the end organ, this was thought to indicate involvement of the vestibular nerve rather than the end organ; therefore they proposed the term "vestibular neuronitis." To the knowledge of the author, the absence of galvanic responses in vestibular neuronitis has not been independently confirmed.

We have found that the body sway response to galvanic stimulation which consists of sway toward the positive electrode (applied to the mastoid area) and away from the negative electrode occurs with much lower stimulus levels than the nystagmic response (Coats, 1969). Because of this lower threshold, body sway responses to unilateral stimulation are always easily obtained. In contrast, the nystagmic response to unilateral stimulation can not be obtained because it requires painful current levels.

By recording the body sway response to galvanic stimulation, a quantitative evaluation of unilateral galvanic responses can be obtained. The amplitudes of the four galvanic responses (right - left - right + left +) to monauricular monopolar stimulation are measured and galvanic directional preponderance and unilateral weakness are computed as with the four caloric responses.

Body sway galvanic tests in two patients with vestibular neuronitis have been obtained. One is presented as case 3. In both patients, a galvanic unilateral weakness on the side of the caloric weakness was present. Thus, our results support those of Dix and Hallpike and suggest that the lesion producing "vestibular neuronitis" does, indeed, involve the vestibular nerve.

CASE REPORTS

The following three cases are representative of the entity vestibular neuronitis, defined as proposed in Section I.

Case 1

This 41 year-old Caucasian housewife with a chief complaint of dizziness, had been in excellent health until one morning, 20 days before the ENG examination, when she felt vaguely dizzy and nauseated with no definite sensation of vertiginous spin. She performed her normal morning activities, but in the afternoon she felt so ill that she went to bed and remained there for

Case 2

This 33-year-old Latin American man was in generally excellent health until six days before the ENG examination, when he noted a light headed feeling while driving to work. This light headed feeling persisted throughout the morning and was accompanied by nausea. He went to bed in the afternoon and experienced some relief but the following morning, after arising, he experienced severe true vertigo, with nausea and vomiting, and entered the hospital. At this time the patient noted a distinct metallic taste on the left side of his tongue. He had a slight roaring in his head, but could not tell whether this was on the right or left side. He did not notice a loss of hearing. There was no history of a recent infection, and the patient had had no medications of any kind.

On admission, the patient appeared acutely ill and showed a second degree spontaneous nystagmus to the right. Ear, nose, and throat examinations revealed no abnormality. Neurological examination results were negative except for the spontaneous nystagmus and a tendency to past point to the left. The spontaneous nystagmus subsided during the patient's hospital stay and, at the time of the ENG examination (four days after admission) it was barely perceptible on extreme right gaze. Tuning fork testing of the patient's hearing revealed no abnormality. Roentgenograms of the petromastoid portions of both temporal bones were normal.

The ENG examination of this patient is shown in Figs. 13 and 14. With eyes closed, an extremely intense right-beating nystagmus was present (Fig. 13) hence the caloric responses (Fig. 14) which are superimposed on this intense nystagmus, show a marked directional preponderance to the right. In addition, the caloric test shows a marked unilateral weakness on the left.

The patient was discharged six days after admission. He was still ex-

Case

This 33-year-old Latin American man was in generally excellent health until six days before the ENG examination, when he noted a light headed feeling while driving to work. This light headed feeling persisted through out the morning and was accompanied by nausea. He went to bed in the afternoon and experienced some relief but the following morning, after arising, he experienced severe, true vertigo, with nausea and vomiting, and entered the hospital. At this time the patient noted a distinct metallic taste on the left side of his tongue. He had a slight roaring in his head, but could not tell whether this was on the right or left side. He did not notice a loss of hearing. There was no history of a recent infection, and the patient had had no medications of any kind.

On admission, the patient appeared acutely ill and showed a second degree spontaneous nystagmus to the right. Ear, nose, and throat examinations revealed no abnormality. Neurological examination results were negative except for the spontaneous nystagmus and a tendency to past point to the left. The spontaneous nystagmus subsided during the patient's hospital stay and, at the time of the ENG examination (four days after admission) it was barely perceptible on extreme right gaze. Tuning-fork testing of the patient's hearing revealed no abnormality. Roentgenograms of the petromastoid portions of both temporal bones were normal.

The ENG examination of this patient is shown in Figs. 13 and 14. With eyes closed, an extremely intense right-beating nystagmus was present (Fig. 13) hence the caloric responses (Fig. 14) which are superimposed on this intense nystagmus, show a marked directional preponderance to the right. In addition, the caloric test shows a marked unilateral weakness on the left.

The patient was discharged six days after admission. He was still ex-

and vomiting. He was admitted to the hospital that evening. The patient gave a history of occasional bilateral, ringing tinnitus and mild hearing loss for about five years. There was no change in auditory function associated with his present illness, no antecedent infection, and no history of ototoxic-drug intake.

Fig. 11 Caloric test, Case 2

perencing some unsteadiness, but his vertigo had almost completely cleared. One week later he was almost completely symptom free but was still experiencing residual unsteadiness which was aggravated by rapid head movement. The patient was tested one month prior to writing this report and, therefore, long term follow up is not available.

Comment. This patient also illustrates the typical picture of vestibular neuronitis, including the relatively gradual onset of vertigo. The case is included because of the history of involvement of taste function on the same side as the vestibular deficit. Also of interest is the nonlateralizable roaring, tinnitus.

Case 3

Five days before the ENG examination this 62-year-old Caucasian man noted a brief mild episode of dizziness which subsequently cleared spontaneously. On the next day he awoke feeling "a little drunk" and by noon he was experiencing severe rotatory vertigo from left to right with nausea

days. (4) Two patients showed evidence of impaired taste function on the side of the vestibular deficit, thus suggesting involvement of the chorda tympani. (5) On two patients, body sway galvanic tests were obtained. Both showed galvanic deficits on the side of the vestibular deficit thus supporting a neural location of the lesion.

Fig 17 Body sway galvanic test, Case 3 Upward pen d deflection represents sway to the right

On admission the patient appeared acutely ill and showed a third-degree spontaneous nystagmus to the right. Ear, nose, throat and neurological examinations were essentially normal except for the spontaneous nystagmus. Roentgenograms of the mastoid portions of the temporal bones were within normal limits. An audiometric examination (Fig 16) showed a mild high frequency loss in both ears, somewhat more pronounced on the right. The spontaneous nystagmus progressively subsided and both it and the vertigo were gone 72 hours after admission.

The ENG examination was done five days after admission. A right bending spontaneous nystagmus of low to moderate intensity was present. It tended to wax and wane throughout the position test so the effect of position could not be reliably assessed. The caloric test showed a severe unilateral weakness on the left (Fig 10).

A body sway galvanic test was done on this patient. The results are shown in Fig 17. There was a significant galvanic unilateral weakness on the left.

Comment: This patient is somewhat older than the usual patient with vestibular neuronitis, but this illustrates that the age incidence is not strictly limited. The galvanic unilateral weakness on the same side as the caloric weakness supports the neural location of the vestibular lesion in vestibular neuronitis.

SUMMARY OF SECTION II

A series of 46 patients with vestibular neuronitis, according to the definition proposed in Section I, was studied. It was found that (1) There was no sex predominance. (2) Some patients complained of tinnitus and fullness, but the incidence of such complaints did not differ significantly from that found in a group of patients with normal auditory and vestibular function. (3) The onset of vertigo typically occurred over a period of hours or even

days. (4) Two patients showed evidence of impaired taste function on the side of the vestibular deficit, thus suggesting involvement of the chorda tympani. (5) On two patients, body sway galvanic tests were obtained. Both showed galvanic deficits on the side of the vestibular deficit, thus supporting a neural location of the lesion.

Fig 17 Bod sway galvanic test, Case 3 Upward pen deflection represents sway to the right

On admission the patient appeared acutely ill and showed a third-degree spontaneous nystagmus to the right. Ear, nose, throat and neurological examinations were essentially normal except for the spontaneous nystagmus. Roentgenograms of the mastoid portions of the temporal bones were within normal limits. An audiometric examination (Fig 15) showed a mild high frequency loss in both ears, somewhat more pronounced on the right. The spontaneous nystagmus progressively subsided and both it and the vertigo were gone 72 hours after admission.

The ENG examination was done five days after admission. A right beating spontaneous nystagmus of low to moderate intensity was present. It tended to wax and wane throughout the position test so the effect of position could not be reliably assessed. The caloric test showed a severe unilateral weakness on the left (Fig 16).

A body sway galvanic test was done on this patient. The results are shown in Fig 17. There was a significant galvanic unilateral weakness on the left.

Comment. This patient is somewhat older than the usual patient with vestibular neuronitis, but this illustrates that the age incidence is not strictly limited. The galvanic unilateral weakness on the same side as the caloric weakness supports the neural location of the vestibular lesion in vestibular neuronitis.

SUMMARY OF SECTION II

A series of 46 patients with vestibular neuronitis, according to the definition proposed in Section I, was studied. It was found that: (1) There was no sex predominance. APPENDIX

STATISTICAL TESTS

The statistical procedures used to obtain the measurements of significance (*P* values) referred to in the text are outlined below. *P* values between .05 and .001 are referred to as "significant" in the text. *P* values of less than .001 are referred to as highly significant. Because patients' ages and amounts of unilateral weakness and spontaneous nystagmus were not normally distributed, nonparametric tests were used. All *P* values are two-tail.

I Incidence of multiple and single attacks

A. Test: Chi square

B. Results

1. Significance of differences among 3 groups (A & V, V-only, Normal)

$\chi^2 = 66.410$ degrees of freedom 3 $P < .001$

2. A & V (110 patients) versus Normal (418 patients)

$\chi^2 = 12.80$ degrees of freedom 1 $P < .001$

3. V-only (76 patients) versus Normal

$\chi^2 = 75.543$ degrees of freedom 1 $P < .001$

4. V-only versus A & V

$\chi^2 = 12.82$ degrees of freedom 1 $P < .001$

C. Conclusion

Significant differences in incidence of multiple versus single attacks exist between all 3 groups.

II Patients' ages

- A. Tests: Kruskal-Wallis one-way analysis of variance for differences among all subgroups. Mann-Whitney U test for differences between individual groups and subgroups. Correction for ties was not employed.

B. Results

1. Significance of differences among 6 subgroups

$H = 12.8$ degrees of freedom 5 $P \sim .023$

2. A & V and Normal, multiple (482 patients) versus A & V and Normal, single (46 patients)

$Z = 0.736$ $P < .237 > .230$

3. A & V and Normal (328 patients) versus V-only, multiple (47 patients)

$Z = 0.793$ $P < .215 > .212$

APPENDIX

STATISTICAL TESTS

The statistical procedures used to obtain the measurements of significance (*P* values) referred to in the text are outlined below. *P* values between .05 and .001 are referred to as "significant" in the text. *P* values of less than .001 are referred to as "highly significant". Because patients' ages and amounts of unilateral weakness and spontaneous nystagmus were not normally distributed, nonparametric tests were used. All *P* values are two-tail.

I Incidence of multiple and single attacks

A. Test: Chi square

B. Results

- 1 Significance of differences among 3 groups (A & V V-only Normal)
 $\chi^2 = 66.410$ degrees of freedom, 3 $P < .001$
- 2 A & V (110 patients) versus Normal (418 patients)
 $\chi^2 = 12.80$ degrees of freedom, 1 $P < .001$
- 3 V-only (76 patients) versus Normal
 $\chi^2 = 75.543$ degrees of freedom, 1 $P < .001$
- 4 V-only versus A & V
 $\chi^2 = 12.82$ degrees of freedom, 1 $P < .001$

C. Conclusion

Significant differences in incidence of multiple versus single attacks exist between all 3 groups.

II Patients' ages

- A. Tests: Kruskal-Wallis one-way analysis of variance for differences among all subgroups. Mann-Whitney U test for differences between individual groups and subgroups. Correction for ties was not employed.

B. Results

- 1 Significance of differences among 6 subgroups
 $H = 12.8$ degrees of freedom, 5 $P = .025$
- 2 A & V and Normal, multiple (482 patients) versus A & V and Normal, single (46 patients)
 $Z = 0.736$ $P < .237 > .230$
- 3 A & V and Normal (528 patients) versus V-only multiple (47 patients)
 $Z = 0.93$ $P < .215 > .212$

- 4 A & V and Normal (28 patients) versus V-only single (29 patients)

$$\chi^2 = 2.962$$

$$P \sim 0.07$$

- 5 V only single versus V-only multiple

$$\chi^2 = 2.213$$

$$P \sim 0.2$$

C Conclusion

The difference in median ages among all subgroups is almost completely accounted for by the tendency for patients in the V-only single-attack subgroup to be younger than patients in the other subgroups

III Incidence and type of infection

A Test Chi square

B Results

- 1 Significance of differences in incidence among 3 groups

$$\chi^2 = 42.963 \quad \text{degrees of freedom} \quad 2 \quad P < 0.01$$

- 2 A & V versus Normal

$$\chi^2 = 5.559 \quad \text{degrees of freedom} \quad 1 \quad P < 0.02 \sim 0.1$$

- 3 V-only versus A & V

$$\chi^2 = 9.243 \quad \text{degrees of freedom} \quad 1 \quad P < 0.005 \sim 0.01$$

- 4 V only versus Normal

$$\chi^2 = 41.230 \quad \text{degrees of freedom} \quad 1 \quad P < 0.01$$

- 5 Incidence of sinusitis in V only multiple group versus incidence in all other patients

$$\chi^2 = 29.149 \quad \text{degrees of freedom} \quad 1 \quad P < 0.01$$

C Conclusion

All groups differ significantly in incidence of infection. The incidence of sinusitis in the V only multiple subgroup is significantly higher than among all other patients

IV Incidence intensity and direction of spontaneous nystagmus

- A Test Chi square Spontaneous nystagmus classified as follows (1) no spontaneous nystagmus (2) spontaneous nystagmus toward LW (3) spontaneous nystagmus away from LW low intensity (4) spontaneous nystagmus away from LW moderate and high intensity

B Results

- 1 Significance of difference between 2 groups

$$\chi^2 = 5.13 \quad \text{degrees of freedom} \quad 1 \quad P \sim 0.02 \sim 0.05$$

- 2 Significance of differences among 4 subgroups

$$\chi^2 = 56.248 \quad \text{degrees of freedom} \quad 9 \quad P < 0.01$$

- 3 A & V single versus V-only multiple

$$\chi^2 = 8.684 \quad \text{degrees of freedom} \quad 3 \quad P \sim 0.10 \sim 0.5$$

- 4 A & V single versus A & V multiple

$$\chi^2 = 1.550 \quad \text{degrees of freedom} \quad 3 \quad P \sim 0.10 \sim 0.5$$

- | | | | |
|---|--------------------------------------|----------------------|------------------|
| 5 | A & V multiple versus V-only single | | |
| | $Z = 1.998$ | degrees of freedom 3 | $P < .05 > .30$ |
| 6 | V-only single versus V-only multiple | | |
| | $Z = 32.187$ | degrees of freedom 3 | $P < .001$ |
| 7 | V-only single versus A & V multiple | | |
| | $\chi^2 = 40.800$ | degrees of freedom 3 | $P < .001$ |
| 8 | V-only-single versus A & V single | | |
| | $Z = 8.187$ | degrees of freedom 3 | $P < .05 > .025$ |

C Conclusion

The difference in spontaneous nystagmus among the subgroups is completely accounted for by the strong tendency for spontaneous nystagmus in the V-only-single-attack subgroup to be relatively intense and directed away from the side of the unilateral weakness.

V Amount of unilateral weakness

- A Tests: Kruskal-Wallis test for differences among all groups; Mann-Whitney U test for differences between individual subgroups. Correction for ties not employed.

B Results

- | | | | |
|---|--|----------------------|------------------|
| 1 | Significance of differences among 4 subgroups | | |
| | $H = 23.971$ | degrees of freedom 3 | $P < .001$ |
| 2 | A & V multiple (91 patients) versus A & V-single (19 patients) | | |
| | $Z = 1.030$ | | $P \approx .294$ |
| 3 | A & V-single versus V-only-single (29 patients) | | |
| | $Z = 0.770$ | | $P \approx .450$ |
| 4 | A & V multiple (91 patients) versus V-only-single | | |
| | $Z = 2.020$ | | $P \approx .043$ |
| 5 | V-only multiple (47 patients) versus V-only-single | | |
| | $Z = 4.218$ | | $P < .001$ |
| 6 | V-only multiple versus A & V multiple | | |
| | $Z = 3.623$ | | $P < .001$ |
| 7 | V-only multiple versus A & V-single | | |
| | $Z = 2.886$ | | $P \approx .004$ |

C Conclusion

The significant difference in amount of unilateral weakness between all subgroups is completely accounted for by the low median unilateral weakness in the V-only multiple-attack subgroup. The difference between the A & V multiple-attack and V-only-single-attack subgroups is of questionable significance because the A & V multiple and A & V-single subgroups do not differ significantly and the A & V-single and V-only-single also do not differ significantly.

V1 Incidence of tinnitus

A *Test Chi square* The significance of the differences in incidence of tinnitus between normal (207 patients) and vestibular neuronitis (46 patients) groups was tested. Also a test was made for significant differences in relative incidence of lateralizable tinnitus, non lateralizable tinnitus and no tinnitus in the normal and vestibular neuronitis groups.

B Results

1 Significance of difference between incidence of tinnitus

$$\chi^2 = 1.70 \quad \text{degrees of freedom } 1 \quad P \approx 0.20$$

2 Significance of differences between incidences of lateralizable, nonlateralizable and no tinnitus

$$\chi^2 = 2.03 \quad \text{degrees of freedom } 2 \quad P < 0.30$$

C Conclusion

The incidence of tinnitus in the normal group does not differ significantly from the incidence in the vestibular neuronitis group. Since there are even smaller differences in incidence of fullness, these differences must also be insignificant.
